Geração e transporte de fundidos em semi-pelitos: modelagem com dados
de campo e pseudosseções

Dissertação apresentada ao Instituto de
Geociências da Universidade de São Paulo
para obtenção do título de Mestre em
Geologia

Área de Concentração:
Petrologia Metamórfica

Orientador:
Prof. Dr. Renato de Moraes

São Paulo
2015

Agradecimentos

Agradeço a CAPES pela bolsa de mestrado concedida e a FAPESP pelo financiamento através dos projetos 10/11152-8 e 13/04007-0. Aos professores e funcionários do Instituto de Geociências, sobretudo aqueles que tiveram participação direta na obtenção dos dados apresentados neste trabalho: Zé Paulo e Samuca na fase de preparação de amostras; Angélica, do Laboratório de microscopia óptica; Sandra e toda a equipe do Laboratório de Química e ICP-MS; Paulinho do Laboratório de Fluorescência de Raios X; Marcos e Leandro do Laboratório de Microsonda Eletrônica; ao Jaime da fotografia; e Claudionor e Henrique da gráfica, que fizeram a mágica final acontecer. Obrigada também às equipes dos laboratórios de microsonda eletrônica da UNB e UFRJ.

Ao professor, orientador e guru metamórfico Renato de Moraes, pelo apoio e orientação mesmo nos momentos mais difíceis, pela paciência e, sobretudo, pela confiança. Muito obrigada! Agradeço também aos professores Mário da Costa Campos Neto pelo apoio através do projeto FAPESP 10/11152-8; Ignez Pinho Guimarães e Lucilene Santos, pela gentil disponibilização do Laboratório de Microscopia do Instituto de Geociências da Universidade Federal de Pernambuco. À Vanja Alcântara, responsável pelo Laboratório de Microscopia da SUREG RE (CPRM), também obrigada pelo apoio.

À minha família, em especial meus pais e seus companheiros, minhas irmãs, e também aos meus tios, primos e avós maternos, pela torcida e apoio incondicionais. Ao meu querido companheiro e muso inspirador, Cofrinho Bittencourt Lima, que não só me amparou em todos os momentos, mas contribuiu fundamentalmente para a realização deste trabalho, participando das etapas de campo, microsonda e edição do volume final da dissertação, além das infindáveis e produtivas conversas geológicas.

Aos queridos amigos que tanto facilitam o caminhar nessa vida: Marco CT, por todo o histórico desde a graduação, mas principalmente por me abrigar e cuidar durante a reta final deste trabalho, juntamente com Johny e Firas, tornando suportável até uma hipergripe de verão; e a curva do rio: André bochecha, Marcião, Jannah Cruz, Rapha Riga, Guga, Dante, Xumaço, Lambe, Xeylah, Daniela Piró, Fio, Paulão Akio, Gal, Pelinha e quem mais eu estiver esquecendo, pela salvação e diversão totalmente garantidas.

Ao pessoal da sala B09, Fofona, Mariana, Pedro, GG, Vanessa e Gustavo, pelo suingue e simpatia. Aos professores Hans Daniel Schorscher e Gustavo Correa Abreu, e todas as pessoas que participaram da disciplina Geologia do Espinhaço nos anos de 2012 e 2013. A todas as pessoas que de alguma forma influenciaram positivamente a execução deste trabalho.

Resumo

Visando contribuir para o entendimento dos processos anatéticos em rochas metamórficas de composição semipelítica, este trabalho apresenta dados de campo e modelagem metamórfica, utilizados como ferramentas para a correlação entre biotita xisto e metatexito ricos em quartzo e plagioclásio, com granada, cianita, muscovita, rutilo e ilmenita, pertencentes à unidade Santo Antônio no Sistema de *Nappes* Andrelândia, sul de Minas Gerais. Com o levantamento de campo foi caracterizada a associação cianita + granada + biotita + plagioclásio + muscovita + rutilo + ilmenita + quartzo + leucossoma tonalítico em litotipos que variam de xisto homogêneo a metatexito protoestromático, com o estabelecimento do protobandamento favorecido pela geração e segregação limitada do leucossoma, que aumenta da base para o topo do pacote. A amostragem dos litotipos principais é feita a partir de três pedreiras, da base para o topo: IC01, em que predomina xisto com feições de fusão *in situ* subordinadas às porções granoblásticas e cristais idiomórficos de plagioclásio em veios de quartzo; IC03, dominada por xisto, na base, e metatexito no topo, com ampla distribuição de *patches*, bolsões e veios de leucossoma tonalítico *in situ* ou *in source*; e IC07, caracterizada pelo bandamento de porções de xisto e metatexito, em escalas de 1 cm a 1 m, com leucossoma *in situ* ou *in source* reforçando o bandamento composicional, ou também na forma de veios, *patches* e bolsões que podem truncar a foliação. Com a química de rocha total é evidente que não existem diferenças composicionais significativas entre xistos e metatexitos. A geração de pequenos volumes de leucossoma rico em Si e Na, compatível com as segregações tonalíticas observadas, e resíduo rico em Fe, Mg e K, associado às acumulações de biotita nas suas bordas, não mudou de forma significativa a composição das rochas. A similaridade entre os padrões de elementos terras-raras reconhecidos para os litotipos analisados indica que a anatexia não alcançou condições altas o suficiente para a dissolução e reprecipitação de fases ultraestáveis como monazita e zircão, hipótese sustentada também pela ausência de feldspato potássico no leucossoma. O cálculo de isopletras resulta em topologia semelhante para amostras de IC01 e IC03; o plagioclásio em amostras das três pedreiras apresenta intervalo composicional contínuo entre An15 e An48, com grãos progressivamente mais ricos em albita, partindo dos inclusos em granada, na matriz xistosa ou metatexítica, e no leucossoma. Esta progressão na quantidade de albita é também observada em cristais de IC01 para IC03 e IC07, respectivamente, sentido no qual, em contrapartida, diminuem as diferenças composicionais entre cristais de mesma amostra e diferentes sítios texturais. A variação composicional da muscovita mostra grupos com distintos teores de sódio, sugerindo trajetória metamórfica horária para o pacote metatexítico e a termobarometria otimizada aplicada a IC01 e IC03 resulta em temperaturas de 750 a 850 °C para o pico metamórfico da base para o topo da unidade, respectivamente, em condições de pressão elevada, maior que 8 kbar. Estas evidências caracterizam o metamorfismo invertido atuante na região e demonstram a importância do reconhecimento da anatexia para a interpretação petrogenética de rochas semipelíticas.

PALAVRAS CHAVE: semipelito, wacke, anatexia, migmatito, metatexito, xisto, tonalito.

Abstract

As a contribution to the understanding of partial melting processes in metamorphic rocks of semipelite composition, this work presents field data and metamorphic modeling. They were used as tools for the correlation between biotite schist and metatexites, which are rich in quartz and plagioclase, with garnet, kyanite, muscovite, rutile and ilmenite, both rocks are correlated to the St. Antônio unit, in the Andreilândia Nappe System, south of Minas Gerais, Brazil. From the rocks field descriptions, it was characterized as the main mineral assemblage kyanite + garnet + biotite + plagioclase + muscovite + rutile + ilmenite + quartz + leucosome with tonalite composition, in rock types ranging from the homogeneous schist to the proto-stromatic metatexite. The compositional banding was enhanced by the generation and limited segregation of leucosome, and its proportion is higher from structural bottom to top of unit. Samples of the main rock types were collected in three quarries, from bottom to top: IC01, schist with sparse *in situ* melting features that are limited to the granoblastic portions and idiomorphic plagioclase crystals in quartz veins; IC03, dominated by schist, at the base, and metatexite, on top, with wide distribution of patches, pockets and veins of leucosome with tonalite composition, *in situ* or in source; and IC07, characterized by the compositional banding, varying from schist to metatexite, in bands with thickness ranging from 1 cm up to 1 m, and either *in situ* or in source leucosome veins enhance the compositional banding, although some veins, patches and pockets truncate the main foliation. With the whole rock chemistry analyses it is evident there are no significant compositional differences between schist and metatexite. The generation of small volumes of silicate Na-rich liquid is compatible with tonalite leucosome, and residue rich in Fe, Mg and K, associated with accumulations of biotite at its edges, but has not changed significantly the bulk rock compositions. The similarity of the of rare earth elements patterns for both rock types indicates anatexis did not reach a high degree and dissolution and reprecipitation of ultra-stable phases, as monazite and zircon, did not happen, which is sustained by absence of potassium feldspar in leucosome. The pseudosection modeling and isopleths calculation result in similar topology for samples of IC01 and IC03. Plagioclase crystals of the three quarries present continuous compositional change, between An₁₅ and An₄₈, with progressively more albite-rich crystals starting from the ones that are enclosed in garnet, in schist, metatexite matrix, and leucosome. This increase in the amount of albite is also observed in crystals from IC01 to IC03 and IC07, respectively, direction which, in turn, decrease the compositional differences between crystals of the same sample and different textural sites. The compositional variation of muscovite allows separation in groups with different quantities of Na, suggesting a clockwork *P-T* path to the rock, and optimized thermobarometry applied to IC01 and IC03 results in temperatures of 750-850 ° C for the metamorphic peak from base to top of the unit, in high pressure conditions, higher than 8 kbar. This *P-T* variation, from bottom to top, characterizes an inverted metamorphism in the region and demonstrates the importance of the recognition of anatexis processes for petrogenetic interpretation of semipelite rocks.

Capítulo I – Introdução

O presente estudo tem como objetivo a investigação do processo de anatexia em rochas semi-pelíticas do Sistema de *Nappes* Andrelândia, pertencentes à unidade Santo Antônio (Trouw *et al.*, 2007), tendo como foco a modelagem do processo anatético e sua relação com os distintos litotipos que a caracterizam: cianita-granada-biotita xistos e metatexitos ricos em plagioclásio e quartzo, com muscovita, rutilo e ilmenita, variando de estrutura xistosa ou protobandada a maciça ou localmente estromática, granulação fina a grossa, e flutuações na quantidade modal dos minerais mencionados.

A partir da abordagem geoquímica de rocha total e mineral obteve-se o cálculo de pseudosseções, isopletras de composição mineral e termobarometria através de geotermômetros e barômetros tradicionais (e.g termômetro granada + biotita, geobarômetro GASP), além de cálculo de equilíbrio *PT* via THERMOCALC (versão 3.33), correlacionando assim as variações de fácies e estruturas observadas e os possíveis processos anatéticos atuantes durante o metamorfismo.

Localização

A área estudada localiza-se no sul do estado de Minas Gerais, entre as cidades de Lambari, Cambuquira e Três Corações, cerca de 300 km a nordeste da cidade de São Paulo e 290 km a sudoeste de Belo Horizonte através da rodovia federal Fernão Dias, a BR-381 (localização com malha rodoviária local na Figura 1).

A cidade de Três Corações foi utilizada como base, e os afloramentos estudados em sua maioria localizam-se a leste da rodovia estadual MG-167 (rodovia Claudionor Vasconcelos, que liga Três Corações a Cambuquira) até o limite com o rio Verde, na sub-bacia de seu afluente rio Lambari, sendo acessados através de estradas rurais a partir da MG-167, da BR-267 (Rodovia Vital Brasil, que liga Cambuquira a Caxambu) ou da BR-460 (rodovia Renato Nascimento, que liga Cambuquira a Lambari).

Revisão bibliográfica

Geologia regional

O Ciclo Panafricano-Brasíliano envolve a fragmentação do supercontinente Rodínia em diferentes ciclos, do Toniano ao Neoproterozóico III (de 1000 a 900Ma, por volta de 750Ma e a 600Ma) interagindo diacronicamente com subducção, formação de arcos magmáticos, colisão e aglutinação entre 840Ma a 490Ma, até o estabelecimento do paleocontinente Gondwana Ocidental (Fuck *et al.*, 2008), que viria a constituir a porção sul de Pangea.

O Cráton do São Francisco, nos limites de Almeida (1977), é o referencial estável principal do Ciclo Brasíliano no Brasil Central, sendo bordejado pelas seguintes províncias neoproterozóicas: Província Borborema a norte, a oeste a Província Tocantins e a leste pela Província Mantiqueira (Figura 2).

Figura 2 - Províncias estruturais do Escudo Atlântico segundo Almeida (1977), extraído de Bizzi *et. al.* 2003.

A região da terminação sul da Província Tocantins é objeto de estudos geológicos desde a década de 1950, quando das primeiras caracterizações de ortognaisses do embasamento por Barbosa (1954) e posterior mapeamento geológico sistemático iniciado por Ebert (1956b), cujos estudos se estenderam até a década de 1980 (1955, 1956a, 1956b, 1958, 1968, 1971, 1984), resultando no estabelecimento dos grupos São João Del Rei, Andrelândia e Varginha (Ebert, 1984).

A porção oriental da região foi compartimentada por Heilbron *et al.* (2000) nos domínios tectônicos Andrelândia, Juiz de Fora e Paraíba do Sul, cujos embasamentos correspondem, respectivamente, aos complexos Mantiqueira, Juiz de Fora e Quirino. O bloco ocidental, caracterizado por Paciullo *et al.* (2000), é compartimentado em três megassequências meso- a neoproterozóicas: São João del Rei, Carandaí e Andrelândia, embasadas em complexos gnáissicos e faixas tipo *greenstone belt*, com diversos corpos ígneos associados.

Duas ideias atualmente estão em discussão para a gênese dos metassedimentos que compõem a porção sul do Orógeno Brasília: *i)* o desenvolvimento de bacias em margem continental intraplaca, a chamada Megassequência Andrelândia, com rochas máficas-ultramáficas como registro de proto-oceanos gerados em ambiente distensivo, e

posterior deformação durante o estabelecimento dos orógenos Brasília (província Tocantins) e Ribeira (província Mantiqueira) no Ciclo Brasileiro (Trouw *et al.*, 1980, 1986, Paciullo, 1997, Paciullo *et al.*, 1993, 2000, 2003); *ii*) ou, a partir do reconhecimento de episódios de subducção e colisão durante o fechamento do paleo-oceano Goianides, quando da convergência da Placa Sanfranciscana sob a Placa Paranapanema (Figura 3; Brito Neves *et al.* 1999, Campos Neto 2000, Mantovani e Brito Neves 2005, Campos Neto *et al.*, 2007, Fuck *et al.*, 2008), a justaposição de rochas depositadas em margens passiva e ativa e agora representadas pelas rochas dos Sistemas de *nappes* Carrancas e Andrelândia, respectivamente (Campos Neto, 2000; Campos Neto *et al.*, 2004).

Figura 3 - ConFiguração paleogeográfica dos fragmentos de Rodínia no Neoproterozóico. 1 - Blocos; 2- Cinturões QPC; 3 - Vulcanossedimentares; 4 - Ofiolitos, 5 - Arcos magmáticos; 6 - Áreas cobertas. Extraído de Fuck *et al.*, 2008. O área delimitada pelo retângulo vermelho indica a localização do orógeno Brasília Meridional.

A Megassequência Andrelândia

Paciullo *et al.* (2003) definem a Megassequência Andrelândia (Figura 4) como uma sucessão metassedimentar de idade neoproterozóica, dividida por descontinuidade estratigráfica em duas sequências deposicionais: uma alóctone no topo, e outra mais basal, autóctone, com rochas meta-ígneas associadas. Baseados nos conceitos de estratigrafia de sequências, Andreis *et al.* (1989 a, b) e Ribeiro *et al.* (1990) definiram o ciclo deposicional Andrelândia, além dos ciclos Tiradentes, Lenheiro, e Carandaí. De acordo com estes ciclos, Ribeiro *et al.* (1995) reconheceram três bacias deposicionais proterozóicas na região: Bacia São João Del Rei (1,8-1,3 Ga), Bacia Carandaí (1,3-1,0 Ga) e Bacia Andrelândia (1,0-0,6 Ga). Segundo os autores, a Bacia Andrelândia representa margem passiva com associações de litofácies alóctones e autóctones, interpretadas como sucessões fluviais (associação 1); trato de sistema transgressivo associado a rifteamento incipiente com geração de magmatismo básico (associações 2 a 4); turbiditos representando períodos de mar baixo e instalação de geleiras (base da associação 5); e sedimentação pelítica gerada pela subida glacio-eustática do mar (xistos homogêneos do topo da associação 5, vide Figura 5).

Figura 4 - Mapa geológico regional com ênfase na distribuição da Megassequência Andrelândia (unidades coloridas), com área de estudo demarcada. Extraído e modificado de Paciullo *et al.*, (2003).

Nessa abordagem, a Bacia Andrelândia seria o registro de margem continental intraplaca entre o cráton São Francisco e o bloco Paranapanema, com evolução partindo de rifteamento (associação A1) com geração de proto-oceanos (associações A2 e A6) até estágios de margem continental passiva (associações A3, A4, A5 e A6); o fechamento da bacia teria evolução por dois estágios colisionais, o primeiro Brasileiro e associado com o desenvolvimento da porção sul da Faixa Brasília e outro posterior relacionado à implantação do Orógeno Ribeira.

Na nota explicativa e mapa 1:100.000 da Folha Andrelândia, Paciullo *et al.* (2003) dividiram a Megassequência Andrelândia nas seguintes unidades, do topo para a base (ver Figura 5): Sequência do Turvo - composta pelas unidades Na6 (biotita-xisto, gnaiss com rochas cálcio-silicáticas e anfibolito intercalado) e Na5 (biotita-xisto); e Sequência Carrancas, com as unidades Na4 (xisto cinza, quartzito subordinado), Na3 (quartzito com mica verde, xisto), Na2 (paragneiss, quartzito, xisto, anfibolito) e Na1 (paragneiss e anfibolito), representadas pelas *nappes* Luminárias e São Tomé das Letras, e pela *klippe* Carrancas (Figura 5).

Figura 5 - Estratigrafia da Megassequência Andrelândia (modificado de Paciullo, 1997, em Paciullo *et al.*, 2003).

Na região de Três Corações, MG, Peternel (2000, 2005) define três conjuntos de unidades: o embasamento, constituído por ortognaisses paleoproterozóicos e *greenstone belts*, provavelmente arqueanos; gnaisses, xistos e quartzitos neoproterozóicos, associados à Sequência Depositional Andrelândia e constituintes das *nappes* Luminárias, São Tomé das Letras, Carmo da Cachoeira, Cambuquira, conjunto de *nappes* de Lambari e *nappe* Varginha; e os granulitos da base da *nappe* Guaxupé.

Estruturalmente o autor reconhece duas fases deformacionais contínuas, DB1 e DB2, e um evento metamórfico (MB) de pressão relativamente alta, que representariam o transporte tectônico de topo para ESE a ENE, sofrido pelas *nappes* durante a colisão relacionada à Faixa Brasília. Duas outras fases deformacionais são reconhecidas, DR1 e DR2, e outro evento metamórfico de pressão mais baixa (MR), relacionados à Faixa Ribeira, com dobramento lateral das *nappes* e posterior geração de zonas de cisalhamento transcorrentes, dúcteis-rúpteis, dextrais, com rumo SW-NE.

Os sistemas Socorro-Guaxupé, Andrelândia e Carrancas

Sob outra perspectiva, o orógeno Brasília Meridional representaria a pilha colisional de *nappes* caracterizada por três domínios tectônicos: o arco magmático, desenvolvido na margem continental ativa da placa Paranapanema e representado pelas rochas de alto grau metamórfico da *Nappe* Socorro-Guaxupé; o domínio continental subductado, correspondente ao sistema de *nappes* Andrelândia e onde se localiza a área de trabalho; e domínios com afinidades de margem passiva ou relacionados à placa Sanfranciscana, correspondentes à *Nappe* Lima Duarte e ao Sistema de *Nappes* Carrancas (Figura 6; Campos Neto *et al.* 2004, 2007).

metapsamitos e gnaisses calciossilicáticos subordinados, metamorfisados em condições de fácies anfibolito de alta pressão, e apresenta lascas de rochas metabásicas retroeclogíticas associadas a rochas metaultramáficas. A infraestrutura destas unidades é representada por ortognaisses paleoproterozóicos, ocorrendo domínio em que a anatexia neoproterozóica foi intensa, resultando no Migmatito Alagoa e intrusões de turmalina leucogranito (Campos Neto *et al.*, 2007).

A *Nappe Andrelândia* é definida por coluna litoestratigráfica com metapelitos dominantes na base, seguidos por metawackes na porção intermediária e sequência metapelito-psamítica no topo (Trouw *et al.*, 2000, Campos Neto *et al.*, 2007), com pico metamórfico em condições de 680 °C e 12 kbar (Santos, 2004). O pacote pode ser subdividido, da base para o topo, em três unidades litoestratigráficas (Campos Neto *et al.*, 2007):

Xisto Rio Capivari, correspondente à série metapelítica de até 750 m de espessura, com intercalações métricas esparsas de metapsamitos e rochas máficas, além de raras intercalações de rochas calciossilicáticas, de até 5 m, na porção oeste da *nappe*. Micaxisto porfiroblástico, com predomínio de biotita sobre muscovita e com porfiroblastos de granada e cianita caracterizam o litotipo mais representativo.

Xisto Santo Antônio, representado pelo pacote intermediário composto por metawackes, com intercalações esparsas e pouco espessas de metapsamitos e rochas máficas, sendo granada-biotita-plagioclásio- xisto/gnaisse o litotipo dominante na unidade, com textura granoblástica e granulação fina a média, em geral equigranular (Trouw *et al.*, 1983). Lentes decimétricas de quartzo, subparalelas à foliação, destacam-se na estrutura homogênea do xisto, enquanto em domínios de temperatura mais alta e nas *klippen* são observadas bandas centimétricas brancas, ricas em plagioclásio, ou a geração de leucossoma envelopado por melanossoma de biotita. Na área tipo, Serra de Santo Antônio, a unidade apresenta espessura média de 850 m; sua ocorrência pode se dar, também, em janelas estruturais sob a *Nappe Liberdade* e define, em *klippen* a SE de Aiuruoca, o *duplex* da *Nappe Andrelândia* (Campos Neto *et al.*, 2007).

Xisto Serra da Boa Vista, topo da coluna ocorrendo regionalmente sobre o Xisto Santo Antônio, podendo repousar sobre o Xisto Rio Capivari. O pacote tem espessura maior que 800 m, subdividido na unidade basal metapsamítica, com muscovita-quartzito e muscovita-quartzo-xisto, reconhecida nas Serras da Boa Vista e Cataguazes; e unidade basal metapelítica, de 750 m, com clorita-cianita-granada-biotita-muscovita

xisto porfiroblástico, que se alterna ritmicamente com camadas de quartzito com até centenas de quilômetros de extensão.

Evolução geológica - contribuições da última década

Visando contribuir para o entendimento dos processos atuantes na formação das rochas do Orógeno Brasília em sua porção meridional e a restrição de sua ocorrência na escala de tempo, desenvolveram-se na última década importantes trabalhos integrando dados petrológicos, estruturais, geoquímicos e geocronológicos das unidades reconhecidas.

Para Reno *et al.* (2009), a aglutinação do Gondwana ocidental teve início no Criogeniano, quando da sutura do arco Socorro-Guaxupé, relacionado ao bloco Paranapanema, à margem continental do cráton São Francisco. Através de termobarometria e modelamento com pseudosseções, foram estabelecidas condições de temperaturas maiores que 900 °C e 15 kbar para o pico metamórfico de ortogranulito da *Nappe* Socorro-Guaxupé. Para as rochas da *Nappe* Três Pontas-Varginha o pico metamórfico foi determinando para três porções do empilhamento, com valores de 12 kbar e 870 °C, na base, 15 kbar e 840 °C, da porção central, e 16 kbar e 900 °C, no topo. O estudo das condições de metamorfismo e suas relações temporais foram ainda enriquecidos com análises de termômetro de Ti em zircão e padrões de ETR em cristais de zircão.

Na base granulítica da *Nappe* Socorro-Guaxupé, parte do arco magmático na placa superior, idade de 622 ± 28 Ma foi determinada para grãos de zircão do leucossoma, interpretada como registro da cristalização do fundido anatético residual durante o resfriamento (Reno *et al.*, 2009). Em amostras do retroeclogito que marca o contato entre as *nappes* Liberdade/Três Pontas-Varginha e Andrelândia/Carmo da Cachoeira, a idade de 678 ± 29 Ma foi determinada em grãos de zircão, interpretados como produto da quebra de piroxênio ígneo durante trajetória *P-T* progressiva. A idade foi interpretada como o momento mais próximo às condições de pico metamórfico e é considerada pelos autores como o tempo mínimo para o descolamento da *Nappe* Três Pontas-Varginha/Liberdade da margem passiva em subducção (Figura 7), bem como para o início da própria orogenia brasileira no sul da Faixa Brasília. Para grãos de zircão formados posteriormente ao pico metamórfico, associados à cristalização do fundido residual em leucossoma nos granulitos de alta pressão da *Nappe* Três Pontas-Varginha, idades de 648 ± 12 e 647 ± 11 Ma foram obtidas (Reno *et al.*, 2009), as quais

se sobrepõem às datações obtidas em rochas metamorfasadas em temperaturas ultra-altas do Complexo Anápolis-Itaçu, norte da Faixa Brasília, e para rochas de fácies anfibolito a granulito do complexo Uruaçu, norte da Faixa Brasília.

Figura 7 - Esquema tectônico do empilhamento das nappes causado pelo descolamento da placa subductada e acreção, segundo Reno *et. al.*, 2009.

Reno *et. al.* (2011) apresentam modelo de evolução retrógrada de alta temperatura para granulitos de alta pressão (Figuras 8 e 9) da *Nappe* Três Pontas-Varginha e *klippe* Carvalhos, e para a *Nappe* Carmo da Cachoeira, cuja evolução metamórfica tem alicerce nas idades obtidas por datação *in situ* do sistema (U-Th)-Pb em monazita. Para a *Nappe* Três Pontas-Varginha a trajetória *P-T* pós-pico compreende segmento de resfriamento isobárico de alta pressão/alta temperatura, seguido por descompressão quase isothermal (~750 °C), e novo segmento de resfriamento quase isobárico de baixa pressão (6,5 kbar). Cada pseudosseção que caracteriza as trajetórias dos granulitos residuais apresenta uma temperatura diferente de *solidus* em alta temperatura/alta pressão, entre 780 e 850 °C, sendo mais baixas as temperaturas reconhecidas nos leucossomas (Figura 8). A descompressão em alta temperatura seria consistente com a ocorrência de cianita primária nas rochas da *nappe*; formação de foliação com sillimanita em gnaisses miloníticos na base e topo da *nappe*; e temperaturas calculadas pela quantidade de Ti em cristais de quartzo da matriz milonítica (Reno *et al.*, 2009). Três grupos de idades foram obtidos para essas rochas - 662-655 Ma, interpretada como registro de estágio tardio do metamorfismo progressivo,

próximo às condições de pico; 640-631 Ma, cujas idades podem representar tanto eventos de recristalização como novo crescimento próximo ao *solidus*; e idades entre 620-588 Ma, sendo as idades mais antigas deste intervalo interpretadas como registro de recristalização pela interação com fundido alojado em fraturas do mineral hospedeiro, idades intermediárias entendidas como recristalização da matriz na trajetória retrometamórfica, e idades mais novas atribuídas à recristalização gerada pela entrada de fluidos advindos dos migmatitos na *Nappe* Carmo da Cachoeira subjacente.

Para a *Nappe* Carmo da Cachoeira, Reno *et al.* (2011) estimaram condições de pico metamórfico entre 700 e 820 °C e 11 a 13,5 kbar, considerando a paragénese quartzo + biotita + granada + plagioclásio + cianita $\pm$ ilmenita + fundido silicático + rutilo (Figura 9). Entretanto, os autores consideram que o pico térmico tenha acontecido em condições superiores, a 900 °C e 13,5 kbar, com geração de feldspato potássico consumido para formar biotita na trajetória retrometamórfica, caracterizada como descompressão isothermal em temperaturas próximas a 670 °C e resfriamento isobárico em 6 kbar. Para a unidade, dois grupos de idades foram reconhecidos: o mais antigo, entre 619 e 616 Ma, é interpretado como registro do crescimento de monazita na cristalização de fundido “*in situ*” no segmento retrógrado de alta pressão da trajetória *P-T*; e o grupo mais novo, de 600 a 595 Ma, que registra o estágio tardio de exumação da unidade. Na *klippe* Carvalhos, interpretada como segmento isolado da *Nappe* Três Pontas-Varginha, foram determinados dois grupos de idades para as rochas, o mais antigo entre 619 e 614 Ma, correlacionável ao evento de recristalização da monazita por interação com fundido em fraturas do mineral hospedeiro reconhecido em amostras da *Nappe* Três Pontas-Varginha; e idades entre 595-563 Ma, relacionadas à superposição da Faixa Ribeira (Reno *et al.*, 2011), embora idades semelhantes tenham sido interpretadas de maneira diferente, como época da exumação, para as rochas *Nappe* Três Pontas-Varginha pelos mesmos autores.

Figura 8 - Pseudosseções simplificadas para 4 amostras da *nappe* Tres Pontas Varginha. Extraído de Reno *et. al.*, 2011.

Motta *et al* (2010) consideram 690 °C e 5,6 kbar como as condições *P-T* de descompressão no campo da sillimanita, calculadas para a paragénese quartzo-muscovita- biotita- granada- sillimanita- plagioclásio na base da *Nappe* Andrelândia, 650 °C e 7,4 kbar para a associação estauroлита- muscovita- biotita- granada- cianita- quartzo- plagioclásio, interpretada como o pico metamórfico da *Nappe* Liberdade, e condições acima de 850 °C e 15 kbar para granulito máfico da *klippe* Carvalhos. Embora as condições metamórficas sejam distintas para os segmentos analisados, os autores apresentam para estas rochas trajetórias *P-T* semelhantes, com sentido horário e importante estágio de descompressão isothermal (Figura 10).

Figura 10 - Trajetórias metamórficas inferidas para as rochas das três estruturas: a. sillimanita-granada-biotita xisto da *Nappe* Andrelândia; b. estauroлита- cianita- granada- biotita xisto da *Nappe* Liberdade; c. granulito máfico da *Klippe* Carvalhos. As curvas das reações ou campossão retirados dos seguintes trabalhos: 1. Spear e Cheney (1989); 2. Spear, Kohn e Cheney (1999); 3. Vielzeuf e Holloway (1988); 4. Green e Ringwood (1967); 5. Ito e Kennedy (1971); 6. Patiño-Douce e Beard (1995). Extraído de Motta *et. al.*, 2010.

Contrapondo a derivação de ambiente em margem passiva interpretada por outros autores, Westin e colaboradores (2011, 2013) realizaram estudos da proveniência sedimentar e sua implicação tectônica para o biotita xisto pertencente à Formação Campestre (Trouw *et al.*, 1980) e à Unidade Biotita Xisto (UBX de Westin e Campos Neto, 2013), correlacionadas ao Grupo Carrancas. O estudo geoquímico das rochas levou em conta o conteúdo de elementos maiores, menores, traço e ETR, a composição isotópica dos sistemas Rb-Sr e Sm-Nd e geocronologia U-Pb em zircão *via* LA-MC-ICP-MS. A partir dos dados foi demonstrada a compatibilidade geoquímica entre a UBX e o Xisto Santo Antônio, que apresentam afinidades com ambiente colisional continental e contribuição de rochas ígneas associadas a arco magmático em sua proveniência, com intervalo de deposição estimado entre 630 e 611 Ma. As idades $^{206}\text{Pb}/^{207}\text{Pb}$ em grãos detriticos de zircão com classe modal de 665 Ma são comparadas às idades obtidas no Xisto Santo Antônio e para o magmatismo básico toleítico precursor de rochas eclogíticas da *Nappe* Liberdade (Campos Neto *et al.*, 2011), sendo interpretadas como época de maior atividade ígnea félsica na área fonte de ambas as unidades. Em contrapartida, as rochas da Formação Campestre têm afinidade de margem passiva, com maior contribuição de sedimentos de crosta siálica antiga.

Na *klippe* Carvalhos, as assinaturas geoquímicas dos granulitos aluminosos (metassedimentares) de alta pressão indicam padrões compatíveis com sedimentos pelíticos e compatibilidade arcoseana para granada-feldspato potássico-plagioclásio gnaiss e granada-biotita-plagioclásio gnaiss, cuja composição apresenta grande similaridade com granada-biotita-plagioclásio xistos/gnaisses reconhecidos nas *nappes* de menor grau metamórfico (Cioffi *et al.*, 2012). Tal similaridade, notável tanto na concentração de elementos maiores e traço quanto em padrões de elementos terras-raras, é interpretada pelos autores como evidência da não extração ou pouca migração do fundido gerado. Os autores estimaram ainda, com o termômetro Zr em rutilo (Tomkins *et al.*, 2007), o pico térmico em 850 °C e pico bórico em 16 kbar, através do geobarômetro GASP (Newton e Haselton, 1981).

Metamorfismo e anatexia

Migmatitos: conceitos e características

De acordo com a definição utilizada pela Subcomissão de Sistemática de Rochas Metamórficas da IUGS, migmatitos (do grego *migma* = mistura, portanto rocha mista) são rochas heterogêneas em escala meso a megascópica, com porções claras de aspecto ígneo e porções escuras de aspecto metamórfico.

A primeira classificação sistemática de migmatitos foi elaborada por Mehnert (1968), que os dividiu em doze tipos estruturais, levando em conta a porcentagem de leucossoma, representante da porção fundida, presente na rocha. O modelo gerador de migmatitos apresentado pelo autor considera o sistema fechado, em que o paleossoma, porção da rocha pouco afetada pela fusão, seria quimicamente equivalente à soma do leucossoma, produto quartzo-feldspático já cristalizado da fusão da rocha, com o melanossoma, resíduo sólido da fusão. Estas duas últimas partes constituem o neossoma. Embora esta classificação seja popular até os dias atuais, sua aplicação no campo não auxilia na produção de mapas geológicos de regiões dominadas por migmatitos e rochas associadas. Assim, Brown (1973) propôs a subdivisão dos migmatitos em apenas dois tipos, *metatexito* e *diatexito*, termos que já existiam, mas que tiveram redefinição para uso mais homogêneo a partir de sua proposta. Como o nome sugere, *metatexito* é a rocha em que as estruturas metamórficas ainda encontram-se preservadas e apresentam coerência e continuidade mapeável, mesmo após a fusão, enquanto no *diatexito* a proporção de fusão é alta o suficiente para que a movimentação do líquido gerado perturbe e destrua as estruturas prévias, de modo que qualquer porção remanescente perca a coerência de orientação.

Estudos realizados desde o final da década de 1980 (*e.g.* Sawyer e Barnes, 1988) mostram que o processo de formação de migmatitos é acompanhado por reações progressivas e formação de fases ricas em vapor d'água; Kriegsman (2001) aponta que modelo mais aceito para este processo corresponde à fusão parcial, com ou sem influxo de fluidos. À partir desta base, o autor mostra que as texturas migmatíticas, moda e química dos minerais são governadas por fusão parcial progressiva e segregação em pequena escala, com extração parcial do fundido, reações retrógradas entre fundido e restito, e cristalização do fundido remanescente com liberação de voláteis. Este modelo mostra a formação de parte do melanossoma durante trajetória de resfriamento, questionando o processo de fusão em sistema fechado tido como base para manter a

equivalência composicional entre paleossoma e o neossoma. Sawyer (2001) discute a geração, segregação, distribuição, movimentação e perda do fundido de escala micro a macroscópica, diferenciando o processo em rochas de fácies anfibolito superior e granulito. Neste trabalho são reconhecidos dois tipos de redes de canais de fundido: a rede de drenagem, que redistribui o líquido nas camadas com a progressão da fusão; e a rede de transferência pela qual o volume coletado deixa a camada fonte. Enquanto que nas rochas da fácies anfibolito parte significativa do fundido permanece na fonte geradora, em granulitos o fundido produzido escapa em quase sua totalidade.

Para White e Powell (2002) a geração, segregação e movimentação do líquido em rochas de fácies granulito interferem diretamente na preservação de minerais característicos do pico metamórfico. Assim, a segregação deste líquido, ou seja, seu isolamento do resíduo sólido e sua perda parcial ou total são fundamentais para a preservação da paragênese do pico metamórfico, que é gradualmente destruída durante o resfriamento, graças à reação em presença do fundido. A pseudosseção do sistema NCKFMASH calculada pelos autores demonstra trajetórias de resfriamento que ilustram a evolução do retrometamorfismo de associação característica de fácies granulito, $grt+sill+crd+ksp$, em presença do líquido silicático gerado na fusão, cuja maior quantidade resulta em maior potencial para a destruição da associação de pico metamórfico (Figura 11). Com base nessa relação, pode-se estabelecer a quantidade necessária de líquido removido para preservação, ainda que parcial, da paragênese de pico. Deve-se ressaltar que este é o modelo é o mais simples apresentado pelos autores, sendo que pseudosseções calculadas para múltiplos eventos de extração do fundido devem melhor representar os processos de fusão na natureza.

Figura 11 - Pseudosseção T-X melt loss para metapelito aluminoso a 805 °C com 40% modal de fusão. As setas de A a D representam distintas trajetórias de resfriamento e suas respectivas associações minerais ao alcançar o *solidus*. X' representa a mínima quantidade de líquido removido para a preservação da paragénese de pico metamórfico. Extraído de White e Powell (2002).

Finalmente, Sawyer (2008) atribui ao termo migmatito implicação genética, definindo-o como a rocha que sofreu fusão parcial *in situ*, de forma que se distinga o neossoma composto por leucossoma (fundido cristalizado) e resíduo, que não necessariamente será melanocrático; e o paleossoma, representante da porção da rocha não (ou pouco) afetada pela fusão. O autor destaca a importância da composição da rocha na geração do neossoma e da influência da perda e/ou ganho de fluidos durante o processo, demonstrando que dificilmente a soma entre neo e paleossoma resulta, de fato, na composição do protólito. Nesta definição, o neossoma da rocha pode ser classificado em duas categorias: não-segregado, no qual o líquido cristalizado e a fase peritética residual estão juntos; e segregado, quando há separação entre leucossoma e resíduo. O leucossoma pode ocorrer *in situ*, quando o líquido permanece onde foi gerado; *in source*, quando o líquido sofre migração, mas permanece na rocha geratriz; ou em veios/diques representados pelo líquido que sofreu migração chegando a intrudir outras rochas, mas ainda contextualizados na região de influência da anatexia.

Outros termos utilizados na descrição de migmatitos são *selvedges*, que consistem em filmes de rocha com diferente cor e associação mineral, separando duas partes do migmatito (e.g. filmes de biotita nas bordas de leucossoma); e *schlieren*, fina camada de minerais tabulares, placóides ou prismáticos alinhados em diatexitos. As feições morfológicas são ainda divididas em dois tipos: de primeira ordem, relacionadas à mudança na estrutura com o aumento do grau metamórfico e à quantidade de líquido produzido; e de segunda ordem, relacionadas não só à quantidade de líquido gerada, mas também à deformação sofrida durante o metamorfismo (Figura 12). Além disso a superimposição de deformação pode gerar feições como veios e dobras, classificados como morfologia de terceira ordem dos migmatitos.

Figura 12 - Classificação dos migmatitos em relação à quantidade de fundido e taxa de deformação. Extraída de Sawyer, 2008.

Em relação ao processo de fusão parcial, Vernon e Clarke (2008) classificam dois tipos de reações: a) reações de fusão saturadas em água, em que a fusão ocorre em presença de água livre; e b) reações de fusão insaturadas em água, quando a fusão se dá sem a presença de fluido e a água é gerada pela quebra de minerais hidratados. No primeiro caso as reações de fusão são congruentes, de forma que todos os componentes vão para o líquido gerado, sem formação de novos produtos sólidos. Em contrapartida,

as reações insaturadas são incongruentes, com consumo de fases minerais hidratadas que liberam água para a formação do fundido insaturado em água, e geração de resíduo sólido, novos minerais, através de reações peritéticas. Segundo os autores, este é o tipo de reação de fusão mais comum para rochas crustais, ocorrendo em condições intensas de metamorfismo, em fácies granulito (800 - 1000 °C). O mineral desidratado e a reação específica associada dependem da composição da rocha, bem como das condições do metamorfismo/fusão, fatores também fundamentais no volume de fundido gerado.

Spear *et al.* (1999) apresentam quatro trajetórias *P-T* hipotéticas para metapelitos no sistema NCKFMASH (Figura 13), analisando a fusão de muscovita e biotita com e sem água em excesso, para condições de pressão intermediária. Em geral, a água é disponível apenas pela desidratação de minerais, pois a baixa porosidade garante que ao deixar a rocha ao longo das reações de desidratação, a água ocorra como ínfimo vapor na região de *solidus*. Assim, a quantidade de fusão que ocorre nesta região é pequena e aumenta de volume à partir do início da reação de fusão por desidratação da muscovita ou biotita. Os autores consideraram rochas com associação mineral dada por granada + biotita + sillimanita + muscovita + plagioclásio + quartzo sob trajetórias de aquecimento e resfriamento, em condições isobáricas de pressões médias e baixas, 5 e 3 kbar, e temperaturas médias, entre 530 °C e 730 °C, além de trajetórias em sentido horário e anti-horário, variando entre pressões aproximadas de 2 a 6 kbar e temperaturas de 650 °C a 750 °C.

Figura 13 - Trajetórias P - T hipotéticas para metapelitos compatíveis com o sistema NCKFMASH. Extraído de Spear *et. al.*, 1999.

Neste modelo, a primeira reação de fusão importante sob aquecimento isobárico em pressões próximas a 5 kbar será a desidratação da muscovita em presença de plagioclásio, gerando aluminossilicato, feldspato potássico e líquido, com assimilação pelo fundido, da água produzida. A progressão do aquecimento resulta em crescimento de granada por meio de reação contínua entre biotita e sillimanita; em contrapartida, o resfriamento nestas condições faz com que a reação opere reversamente, com granada sendo consumida para a geração de biotita e sillimanita retrometamórficas. Isto é possível graças à cristalização do fundido, que fornece a água necessária para a reação inversa responsável pela geração de *selvedges* (acumulações de minerais retrometamórficos nas bordas do leucossoma ou dispersos na matriz da rocha), como proposto pelo modelo de Kriegsman (2001). A cristalização total do fundido liberaria a água remanescente formando muscovita retrometamórfica e assim rochas neste contexto seriam caracterizadas por leucossoma abundante e disperso, com *selvedges* de biotita e sillimanita, e núcleos com muscovita tardia ou mesmo cortando toda a foliação. Ainda em trajetória isobárica, porém em condições de pressão de 3 kbar, o início da fusão se dá por quebra de muscovita, granada é produzida pela reação entre biotita e sillimanita, porém a progressão do aquecimento resulta, neste caso, na produção de cordierita. A partir desse momento, o desenvolvimento de granada se dá por reação entre biotita e

cordierita, caso a sillimanita seja consumida primeiro, ou entre cordierita e feldspato potássico, com biotita consumida primeiro. O retrometamorfismo de granada pode dar origem a coroas de cordierita e as rochas serão ricas em feldspato potássico e sem muscovita retrometamórfica.

Considerando a trajetória *P-T* horária com pressão inicial próxima de 6 kbar e temperatura máxima alcançada de 750° C, a progressão do metamorfismo é semelhante àquela observada inicialmente na primeira trajetória isobárica, até que no campo de alta temperatura e baixa pressão a granada passa a ser consumida gerando cordierita retrometamórfica, como na segunda trajetória isobárica. Dessa forma, rochas deste contexto têm leucossoma com feldspato potássico, relações texturais complexas entre leucossoma e porfiroblastos de granada e cordierita e sem muscovita retrógrada. Finalmente, considerando a trajetória *P-T* antihorária, o feldspato potássico é gerado pela desidratação de muscovita e o crescimento de granada está associado à reação entre biotita e sillimanita. A produção de líquido ocorre pela reação entre biotita e/ou feldspato potássico com cordierita, proporcionando o desenvolvimento da granada. Com o aumento da pressão, a cordierita é consumida e biotita e sillimanita são produzidas pelo retrometamorfismo de granada através da liberação de água pela cristalização do líquido, até a geração de muscovita diretamente do fundido remanescente. Estas rochas apresentam feldspato potássico disperso na matriz e muscovita tardia no leucossoma e cortando as estruturas prévias, além de granada de várias gerações e cordierita reliquiar.

Com base neste estudo os autores afirmam que o volume de líquido produzido por uma reação de desidratação é função de dois fatores: quantidade de água liberada pela reação (dependente da estequiometria) e quantidade de água do fundido nas condições de interesse. Em quantidades modais, rochas com 10 a 20% de muscovita produzem de 7 a 14% de líquido. Sob altas pressões e temperaturas moderadas, rochas com esta composição podem produzir apenas 1 a 2% de fundido, o que pode ser de difícil identificação. Em relação à quebra da biotita, composições entre 10 e 20% do mineral podem produzir entre 7 e 14% de líquido, enquanto sob condições de altas pressões e temperaturas até 26% de fundido pode ser gerado (Spear *et al.*, 1999).

Modelagem metamórfica

Powell *et al.* (2009) classificam a modelagem do equilíbrio de rochas metamórficas em dois tipos: modelagem inversa, na qual se interpreta a paragênese principal através de observações, obtendo-se as composições dos minerais para

aplicação de métodos de termobarometria tradicionais, a fim de determinar as condições *PT* para a associação em questão; e a modelagem direta, que através da composição de rocha total permite o cálculo de pseudosseções para consideração das condições e processos de geração envolvidos. A termobarometria, por sua vez, pode ser obtida através de reações diretamente calibradas, como na termometria calculada pela troca de ferro e magnésio em granada e biotita ou o geobarômetro GASP, baseado nas trocas de cálcio e alumínio entre granada, aluminossilicato e plagioclásio; termobarometria otimizada, com base em reações múltiplas obtidas através de banco de dados internamente consistente; ou pelo cálculo de pseudosseções, através do estabelecimento dos campos de estabilidade mineral e cálculo de isopletras composicionais e de moda mineral.

Dois métodos podem ser utilizados para o cálculo do equilíbrio por pseudosseções: minimização da Energia Livre de Gibbs para reconhecimento das paragéneses em equilíbrio, cujo método de interpolação permite a localização dos campos de estabilidade e a construção direta do diagrama, embora possa haver problemas com o estabelecimento dos limites dos campos identificados e limitação no reconhecimento de campos restritos (e.g. PERPLEX, Connolly 1990, 2005, 2009, e Connolly *et. al.*, 1987, 2002); e solução via equações não lineares, através da qual o diagrama é calculado linha por linha, apresentando resultado confiável em relação aos campos de estabilidade e seus limites estabelecidos (THERMOCALC, Powell e Holland, 1988).

No presente trabalho a abordagem do metamorfismo é baseada no cálculo de pseudosseções através do *software* THERMOCALC (Powell & Holland, 1988; banco de dados internamente consistente de Holland e Powell, 1998), com modelamento de isopletras composicionais para biotita, granada, muscovita, plagioclásio e fundido, e termobarometria otimizada para composições associadas ao pico metamórfico das rochas estudadas. Adicionalmente foram calculados resultados de pressão e temperatura através do geobarômetro GASP e termobarômetros de granada + plagioclásio + muscovita + biotita, baseados no banco de dados internamente consistente de Powell e Holland (1998). O barômetro GASP baseia-se na reação $\text{Ca}_3\text{Al}_2\text{Si}_3\text{O}_{12} + 2\text{Al}_2\text{SiO}_5 + \text{SiO}_2 = \text{Ca}_3\text{Al}_2\text{Si}_2\text{O}_8$ que, considerando a reação de equilíbrio $\Delta G_{P,T} = \Delta H_{1,T} - T \cdot \Delta S_T + (P-1) \cdot \Delta V + RT \cdot \ln K = 0$ (Spear, 1993) associada aos dados termodinâmicos, pode ser descrita como $7635 - 19.66T + 0.7963(P-1) + 3T \ln(X_{\text{Ca,Pl}}/X_{\text{Ca,Grt}}) = 0$. A influência das micas foi considerada através da utilização do termômetro granada + biotita, baseado na

reação $\text{Fe}_3\text{Al}_2\text{Si}_3\text{O}_{12} + \text{KMg}_3\text{AlSi}_3\text{O}_{10}(\text{OH})_2 = \text{Mg}_3\text{Al}_2\text{Si}_3\text{O}_{12} + \text{KFe}_3\text{AlSi}_3\text{O}_{10}(\text{OH})_2$, $6266 - 2.35T + 0.029(P-1) + 3\text{In}K_D = 0$ considerando os dados termodinâmicos e a calibração de Battacharya *et al.* (1992); e dos barômetros de granada + plagioclásio + muscovita + biotita (GPMB-Fe/Mg). O cálculo das condições *PT* via tais termobarômetros tradicionais foi realizado através em planilha EXCEL[®] disponibilizada por White (2004).

Materiais e métodos

Esse trabalho é a continuidade de projeto de iniciação científica e trabalho final de graduação da autora (Batista, 2011), portanto os dados quantitativos apresentados aqui são integrados aos destas etapas de trabalho anteriores.

A partir da base cartográfica de Peternel (2000) e mapa geológico do mesmo autor (no relatório Geologia da Folha Varginha, SF-23-V-D-VI, 1:100:000, Trouw *et al.* 2007), foram levantados 67 afloramentos relacionados às unidades geológicas regionais (ver mapa geológico e de pontos, anexo 1) e 7 pequenas pedreiras de brita, a maioria desativadas, com exceção da pedreira IC-03 (Pedreira INCOPE); com coleta de amostras de rocha e dados estruturais com ênfase na unidade Santo Antônio.

A localização dos pontos e orientação geográfica para os trabalhos de campo foram obtidas através do auxílio de Sistema Global de Posicionamento (*GPS* na sigla em inglês), por meio do equipamento Garmin ETREX[™], e por imagens de satélite e mapas disponibilizados por Google[™] e Google Earth[™]. As fotografias dos afloramentos foram capturadas com câmera digital Nikon Coolpix[™]. Após serem serradas, as amostras foram fotografadas no laboratório de fotografia do IGC/USP, com o auxílio do fotógrafo Jaime de Souza Marcos.

Para revisão bibliográfica, os trabalhos consultados foram selecionados na biblioteca do IGC/USP, além de consultas efetuadas em sites de periódicos (e.g. *Precambrian Research*, *Journal of Petrology*, *Journal of Metamorphic Geology*) e em materiais de acervo pessoal. A petrografia foi desenvolvida em sua maior parte nos laboratórios de microscopia óptica do Instituto de Geociências da Universidade de São Paulo (IGC/USP), tendo sido também utilizados os laboratórios do Instituto de Geociências da Universidade Federal de Pernambuco (UFPE) e do Serviço Geológico do Brasil – Superintendência Regional de Recife (CPRM-SUREG/RE).

Das amostras coletadas nas pedreiras relacionadas à unidade Santo Antônio, vinte e três foram selecionadas para análise química de rocha total por Fluorescência de Raios X

(equipamento Philips, modelo PW2400), e quantificação dos elementos terras raras por espectrometria de massa com plasma induzido acoplado (ICP-MS – espectrômetro do tipo quadrupolo, modelo ELAN 6100DRC/PerkinElmer/Sciex), visando avaliar as variações químicas entre os diversos litotipos relacionados à unidade.

Para a realização destes ensaios os seguintes passos foram seguidos para preparação das amostras: a) fragmentação com marreta e separação das porções alteradas; b) diminuição da granulação em prensa hidráulica; c) pulverização em moinho de anéis de ágata durante 30 min, resultando em um pó de granulometria inferior a 200 mesh; c) separação de alíquotas de 7,0g, micronizadas em álcool com cilindros de ágata durante 20min, obtendo-se granulometria menor do que 5 μm ; d) secagem em estufa a 60° C durante dois dias; e) adição de 1,4g de cera, homogeneização e prensagem, obtendo-se pastilhas com 40 mm de diâmetro para análise de elementos traço; f) separação (após a moagem) de alíquotas de 1,0g de amostra, com adição de 9,0g de fundente (mistura 4:1 de metaborato de lítio e tetraborato de lítio); g) fusão a temperatura de 1000°C, resultante, após resfriamento, em discos de vidro com cerca de 40 mm de diâmetro para análise de elementos maiores e menores. Durante todo o processo de preparação, os equipamentos foram limpos a cada amostra com álcool etílico ou acetona para evitar possíveis contaminações.

As análises de química mineral foram realizadas na Universidade de São Paulo (USP), Universidade de Brasília (UnB) e Universidade Federal do Rio de Janeiro (UFRJ). No laboratório da USP foram realizadas as análises de rutilo, com equipamento JEOL JXA-FE-8530, com canhão eletrônico suportado por Field Emission (FE), que permite a melhor resolução espacial da atualidade. As demais análises foram realizadas na Universidade de Brasília (IGc/UNB) e Universidade Federal do Rio de Janeiro, com microsonda modelo JEOL JXA-8230, sempre sob voltagem de aceleração de 15 kV, corrente do feixe de elétrons de 20,1 A, diâmetro do feixe de 5 μm , tempo médio de contagem de 20 segundos e correções do tipo PROZA.

A partir dos dados de química de rocha total, duas amostras, uma da pedreira IC-01 e outra da IC-03, foram selecionadas para o cálculo de pseudosseções e isopletas, realizados com o programa THERMOCALC v3.33 (Powell & Holland, 1988), usando banco de dados termodinâmicos atualizados em 2008 (Holland e Powell, 1998). Além da modelagem com as pseudosseções e isopletas, as condições *P-T* de pico metamórfico foram calculadas a partir de geotermobarômetros tradicionais (termômetro de granada + biotita, barômetros GMPB-Mg, GMPB-Fe e barômetro GASP), termômetro de Zr em

rutilo (Zack *et al.*, 2004; Watson *et al.*, 2006; Ferry e Watson, 2007; Tomkins *et al.*, 2007) e através do cálculo de equilíbrio via THERMOCALC v3.33, utilizando os dados de química mineral obtidos via microsonda.

Capítulo II – Geologia local

O levantamento da geologia local teve como base cartográfica o mapeamento de Peterneil (2000) e Trouw *et al.* (2007) e, além do reconhecimento das unidades regionais aflorantes, o trabalho teve como ênfase a caracterização dos xistos e paragneisses associados à unidade denominada por estes autores de unidade Santo Antônio, com ênfase nas pedreiras denominadas doravante como IC01, IC03 e IC07. Os pontos e estruturas, assim como a articulação das unidades em mapa e seção geológica, são apresentados nos mapas do Anexo 1.

Para composição do mapa geológico (Anexo 1), foram respeitados os contatos de Trouw *et al.* (2007), exceto na porção centro-norte da área, onde a área mapeada como Unidade Arantina foi significativamente diminuída, restringida aos de afloramentos de granada-biotita-muscovita xistos ritmicamente intercalados com muscovita quartzitos e muscovita quartzo xistos, alojados em sinforme sin S_2 (D_2), no topo estrutural da área. Os biotita xistos e paragneisses a granada e cianita, com muscovita e ricos em plagioclásio e quartzo, associados por estes autores à unidade Arantina na região da pedreira IC03, foram interpretados como topo metatexitico da unidade Santo Antônio, interpretação discutida ao longo do presente trabalho.

As unidades estão organizadas em pilhas de *nappes*, com imbricações suhorizontais sin- S_2 evoluindo para cavalgamentos pós S_3 . A unidade Ortognaisse Migmatítico aflora sobre paragneisses da unidade São Vicente, como lente alóctone da infraestrutura ortoderivada, possivelmente correlacionável ao Complexo Mantiqueira. Os quartzitos da unidade São Tomé, correspondente ao sistema de *nappes* Carrancas, estão em contato lateral com o paragneisse São Vicente, este com associação de anfíbolitos e muscovita quartzo xistos, biotita xistos, e metarritmitos, formando com as unidades Santo Antônio e Arantina, sotopostas, o correspondente ao sistema de *nappes* Andrelândia.

Unidade Ortognaises Migmatíticos

Aflora a sul da cidade de Cambuquira, na bacia do córrego Miranda, no fundo do vale e encostas de morrotes e da serra das Águas, em contato de cavalgamento sobre

paragneisses da Unidade São Vicente. A caracterização desta unidade não é objetivo deste trabalho, sendo reconhecidos apenas três pontos relativos a ela.

Nos pontos visitados a rocha é caracterizada por cor cinza clara, granulação média, e composta por quartzo, plagioclásio, feldspato potássico, biotita e epidoto, com bandamento gnáissico bem definido, alternando bandas centimétricas quartzo-feldspáticas granoblásticas e bandas de biotita, lepidoblásticas, ocorrendo também lentes monominerálicas de quartzo. Ocorrem injeções graníticas leucocráticas de textura grossa paralelas ao bandamento. Na serra das Águas, em contato com a Unidade São Vicente, apresenta forte foliação milonítica.

Trouw *et al.* (2007) reconhecem nesta unidade ortogneisses bandados; ortogneisses migmatíticos e ortogneisses diatexíticos, com composição mineralógica variando de biotita-(granada) gnaisses a hornblenda-biotita-(granada) gnaisses, com variação composicional desde sienogranito até tonalito. Relatam ainda intercalações lenticulares de anfibolitos e metaultramáficas.

Unidade São Tomé das Letras - Quartzitos com intercalações de quartzoxistos.

Esta unidade aflora no extremo sudeste da área, sustentando a serra de São Domingos ou Bocaina, intercalado tectonicamente com os paragneisses da Unidade São Vicente. Trata-se de quartzitos a muscovita quartzo xisto granoblástico, com foliação marcada por planos lepidoblásticos de muscovita e pelo estiramento dos grãos de quartzo. Trouw *et al.* (2007), descrevem como acessórios turmalina e opacos, e relatam a maior frequência de muscovita xistos no topo da unidade.

Embora estes autores considerem a unidade São Tomé das Letras como concordante e gradacional sobre a unidade São Vicente, a relação estrutural da área sugere intercalação tectônica entre os pacotes, de forma que neste trabalho optou-se por considerar essa unidade como pertencente a *nappe* São Tomé, integrante do sistema de *nappes* Carrancas.

Unidade São Vicente - Biotita paragneisse bandado, localmente migmatítico, com intercalações de quartzito, muscovita-quartzo xisto e anfibolito

Aflora a sul da cidade de Cambuquira, sob a unidade Ortogneisses Migmatíticos, intercalada tectonicamente com os ortogneisses e a unidade Santo Antônio na encosta da serra das Águas, e com a unidade São Tomé das Letras na serra de São Domingos ou Bocaina.

Predominam granada-biotita-muscovita gnaisses bandados, com alternância de camadas quartzo-feldspáticas, mais ou menos ricas em biotita. De acordo com Trouw *et al.* (2007), as camadas pobres em biotita têm granulometria média à grossa e podem conter grânulos e seixos finos arredondados, de quartzo, feldspatos e litoclastos plutônicos, quartzo-feldspáticos. São rochas ricas em plagioclásio e quartzo, com quantidades variáveis de biotita, muscovita, epídoto, microclínio e localmente granada. Minerais opacos, allanita, apatita, zircão, titanita, rutilo, carbonato e anfibólio são descritos como fases acessórias. Os autores descrevem ainda intercalações de rochas metamáficas e metaultramáficas, não descritas nos levantamentos deste trabalho.

No contato superior com a unidade Santo Antônio, no lado sudeste da serra do Cigano, ocorrem muscovita-quartzo xistos e um corpo de anfibolito de proporções mapeáveis em escala 1:100.000 (unidade São Vicente - muscovita quartzo xistos e quartzitos e unidade São Vicente – anfibolitos, respectivamente), provavelmente correlacionada à denominada “associação superior” de Trouw *et al.* (2007), caracterizada como comuns intercalações de muscovita xistos associados com quartzitos, biotita xistos, anfibolitos e escassos mármores ou xistos carbonáticos. Os afloramentos desta associação são intensa e invariavelmente alterados para cores que variam de vermelho a marrom, ocre e amarelo, com granadas e quartzo ressaltados nas superfícies intemperizadas.

Unidade Santo Antônio - Biotita xisto/metatexito rico em plagioclásio, com granada, cianita, rutilo, muscovita e ilmenita.

Principal unidade aflorante na região estudada, a unidade Santo Antônio sustenta as serras da área central do mapa, como as serras do Palmital, dos Tapajós e do lado noroeste da serra do Cigano, a leste da cidade de Cambuquira, em contato inferior com a unidade São Vicente e contato superior com a unidade Arantina.

De forma geral, são biotita xistos ricos em plagioclásio e quartzo, com muscovita, cianita, granada, ilmenita e rutilo, ocorrendo tanto níveis com foliação bem marcada pelas micas (biotita>>muscovita) predominantes, quanto com aspecto homogêneo (maior porcentagem de plagioclásio e quartzo), com frequentes veios de quartzo paralelos a foliação principal. Apatita, zircão e monazita são fases acessórias comuns.

Estas rochas possuem estrutura xistosa a protobandada gerada pela alternância de lâminas de textura lepidoblástica definidas por biotita, e lâminas quartzo-feldspáticas

que definem porções granoblásticas e granulação variando de fina a grossa. Cianita e granada associam-se às bandas lepidoblásticas de biotita com muscovita subordinada, em quantidades e tamanhos variáveis ao longo do pacote, ocorrendo desde porções onde a cianita é fina e escassa ($<0,3\text{mm}$, $<5\%$) até zonas em que este mineral encontra-se homogeneamente distribuído, bem formado, com cristais euédricos de até 2 mm. A granada ocorre como porfiroblastos que variam entre 0,5 mm e 1 cm de diâmetro, em quantidades de 5 a 15%. Quartzo e plagioclásio perfazem de 20 a 50% da rocha.

Esta variação, associada à variação na quantidade de biotita, entre 20 e 40%, condiciona o aspecto do afloramento das rochas desta unidade. Nas regiões de baixada, com afloramentos escassos e bastante alterados, ocorrem os xistos com foliação proeminente, franca predominância de biotita e subordinação das fases granoblásticas; domínios homogêneos, com maior quantidade de quartzo e plagioclásio, afloram nas encostas e por vezes compõem os topos das serras, como lajes de dimensões métricas, por vezes arredondadas, conhecidas popularmente como “baleias” de rocha.

Lentes e veios localmente pegmatóides compostos de composição tonalítica, descontínuos, paralelos ou levemente oblíquos à foliação, são comuns e apresentam contatos mais abruptos. Também são comuns megacristais de plagioclásio dispersos na matriz, por vezes sigmoidais; e porfiroblastos de granada com feições de coalescência, envoltas por coroas/filmes de plagioclásio, interpretadas como cristalização de filmes de fusão *in situ*; ou com coroas de biotita, interpretadas como possível retrometamorfismo durante a cristalização de fusão *in situ*. Veios de quartzo de espessura centimétrica e comprimentos variáveis, às vezes com mais de 1 metro, concordantes ou truncando a estrutura principal da rocha, muitas vezes em dobras intrafoliais ou formas sigmoidais, são penetrativos em todo o pacote. A ocorrência destas estruturas concordante e discordantemente da estrutura principal evidenciam a diacronicidade de geração de fluidos em relação à fase de deformação principal.

O protobandamento é paralelo à foliação principal S_2 , anastomosada, com pares SC recorrentes em todos os afloramentos, e planoaxial de dobras intrafoliais e de crenulação penetrativa. Localmente observa-se a transposição desta estrutura segundo crenulação caracterizada por dobras assimétricas com planoaxial de alto ângulo (S_3), gerando foliação posterior.

Variações na granulação, estrutura e moda destes minerais, associados às feições de fusão *in situ* e *in source*, são interpretadas como oriundas de processo anatético incipiente a moderado, do topo para a base do pacote. As pedreiras IC-03 e IC-07,

relacionadas por Trouw *et al.* (2007) às unidades Arantina e Santo Antônio, respectivamente, foram interpretadas como domínios metatexíticos similares, compondo o topo mais fundido da unidade Santo Antônio. A caracterização das pedreiras estudadas em detalhe, IC01, IC03 e IC07, e a decorrente modelagem metamórfica obtida para seus litotipos, apresentadas nas próximas seções, servem como base argumentativa para esta interpretação.

Unidade Arantina - Intercalações submétricas de muscovita quartzo xistos, quartzitos e biotita xistos com granada e plagioclásio.

Na porção centro norte da área, em contato concordante com a unidade Santo Antônio, afloram granada-biotita-muscovita xistos ritmicamente intercalados com muscovita quartzitos e muscovita quartzo xistos, em sucessões de camadas lenticulares com espessura de 5 cm a 1 m, comumente subdecimétricas. Para esta unidade Trouw *et al.* (2007) descrevem ainda anfibolitos, quartzitos manganesíferos e rochas calcissilicáticas, não descritas nos levantamentos desse trabalho.

Pedreiras estudadas em detalhe

IC01 – Pedreira desativada de Cambuquira, MG

Na estrada entre Cambuquira e Caxambu, próximo ao ponto de intersecção entre as rodovias BR-267 e MG-456 ocorre pedreira abandonada, em que afloram rochas de cor cinza escura, com foliação anastomosada, homogênea, com lentes ou veios de quartzo com pouco plagioclásio associado. A textura da rocha é lepidogranoblástica (Figura 14) e sua composição é dada por quartzo, plagioclásio e biotita, compondo a matriz, enquanto que muscovita está associada a veios de quartzo ou em planos preferenciais paralelos ao bandamento; cianita, como cristais incolores de até 4 mm, e porfiroblastos de granada, com diâmetro médio de 5 mm e máximo de 6-8 mm, ocorrem dispersos na rocha.

Localmente variações na proporção de biotita pode imprimir à rocha bandamento composicional discreto. Os cristais de cianita estão dispostos no plano da foliação, mas nem sempre acompanham a direção da lineação mineral definida por muscovita e biotita, paralelas aos eixos de crenulação da estrutura principal. Cristais maiores de plagioclásio são comuns e podem ser ou remanescentes de grãos detríticos, ou porfiroblastos, o que é mais provável, pois se apresentam recristalizados. Tais relações minerais e estruturais permitem classificar a rocha como cianita-granada-

muscovita-quartzo-plagioclásio-biotita xisto. A paragénese observada em campo é quartzo + muscovita + plagioclásio + cianita + biotita, típica da zona da cianita, acima das condições de quebra da estaurolita.

Figura 14 - Aspecto geral da pedreira (à esquerda); porfiroclasto de plagioclásio (à direita).

O plano principal de foliação tem atitude N55E/21NW com duas lineações de crenulação: a mais antiga, subhorizontal N60E/01, outras posterior N16E/15, ambas acompanhadas por orientação das micas. Veios, bolsões e porfiroclastos sigmoidais indicam transporte de topo para NE. Os veios de quartzo, com espessura máxima de 5 cm, podem alcançar até 15% do volume em rocha, o que é significativo. Podem se orientar segundo estruturas variadas, ora concordantes com a foliação, subparalelos ou dobrados, além de variações em formas boudinadas e sigmoidais (Figura 15a, b, c, d, e). Além dos veios, ocorrem bolsões com até 60 cm de espessura (Figura 15f), compostos por quartzo, com feldspato e megacristais de muscovita associados, mas subordinados. Eventualmente, estes bolsões estão deformados em formas sigmoidais.

Figura 15 - Distribuição dos veios de quartzo e relações com a encaixante. A: dobras intrafoliais; B: boudin; C e D: dobras transpostas concordantemente à foliação; E: veios oblíquos à foliação; F: indicador cinemático gerado por bolsão quartzo-feldspático deformado.

Ao microscópio a rocha apresenta plagioclásio (20 – 35%), quartzo (10 – 20%), biotita (25 - 40%), granada (5 – 15%), cianita (2 – 10%), muscovita (2 – 8%), e rutilo, ilmenita, zircão, monazita, sillimanita, turmalina e apatita como minerais acessórios; carbonato ocorre em veios microscópicos tardios, cortando a foliação. A estrutura é definida por foliação anastomosada, em que a biotita está concentrada em leitos que definem a foliação e contornam domínios sigmoidais ou amendoados de quartzo e plagioclásio; a sillimanita é muito fina, ocorrendo como fibrolita em diminutos feixes

aleatórios nos contatos entre os cristais de quartzo e plagioclásio das porções granoblásticas. A textura é granolepidoblástica, localmente protomilonítica.

A quantidade de quartzo na matriz condiciona a estrutura observada nas amostras, de forma que nos exemplares onde este mineral é abundante na matriz (IC-01-A2 – Figura 16– IC-01-C2 e IC-01-D2), a biotita apresenta-se subordinada, em placas finas, e a rocha é granoblástica e homogênea; nas amostras em que apresenta quartzo subordinado na matriz (IC-01-B2 – Figura 16 – IC- 01-E3 e IC-01-F3), a estrutura é anastomosada, definida por pares “SC” de micas que evidenciam a atuação de deformação não coaxial.

O plagioclásio da matriz apresenta zanação óptica bem desenvolvida, concêntrica ou não, e bordas recristalizadas. Esses cristais com extinção concêntrica muito intensa são interpretados como sendo de origem ígnea. Estes cristais podem ocorrer associados aos veios de quartzo, onde se apresenta como megacristais isolados, ou como pequenos bolsões nas bordas, ou na porção interna dos veios (Figura 16), onde apresentam hábito mais idioblástico. Dentro dos veios, é comum que vários cristais de quartzo se apresentem em continuidade óptica (Figura 16 – IC-01-D2), o que pode sugerir cristalização a partir de líquido, como os de plagioclásio associados. A muscovita é abundante macroscopicamente, embora ocorra em planos e camadas preferenciais no pacote, enquanto nas seções delgadas ocorre subordinada à biotita, podendo ou nas bordas dos veios de quartzo com plagioclásio. Tais feições são consideradas como indicativas do alcance do campo de fusão, de forma que quartzo e plagioclásio ígneos representariam a cristalização de leucossoma “*in situ*”, enquanto a muscovita poderia representar fase residual ou retrometamórfica.

Figura 16 - Feições de fusão associadas às rochas de IC01: condicionamento da estrutura relacionado à quantidade de quartzo na matriz (IC01A2 e B2); geração de lentes e acumulações de plagioclásio ígneo em borda (IC01C2) e plano interno (IC01D2) de veios de quartzo, este localmente na forma de vários cristais em continuidade óptica IC01(D2); geração de plagioclásio ígneo em borda de veio (IC01E3); e bolsão de plagioclásio ígneo na matriz (IC01E3).

IC03 – Pedreira INCOPE, Três Corações, MG

A Pedreira INCOPE fica localizada na saída leste de Três Corações, na estrada para Cambuquira. A rocha é cinza clara, de granulação grossa a muito grossa, com veios de quartzo ou quartzo-feldspático subparalelos à foliação e lentes pequenas quartzo-feldspática disformes com contatos transicionais para a encaixante. A textura é lepidogranoblástica, gerada pelo notável aumento na quantidade de feldspato e quartzo

em relação à pedreira IC-01, bem como pela maior granulação, embora porções mais finas ainda preservem bandamento fino, que é paralelo à estrutura principal, a xistosidade de atitude N44E/47SE. A foliação em todo o pacote é anastomosada, com leitos lepidoblásticos ricos em biotita ou localmente muscovita, que envolvem domínios ricos em quartzo ou quartzo + plagioclásio, destacando pares SC. Os porfiroblastos de granada apresentam foliação interna discordante da estrutura principal, mas muitas vezes em continuidade com a foliação externa, o que evidencia que foram rotacionados; suas bordas apresentam alteração para biotita, quando próximas às porções quartzo-feldspática, que por sua vez destacam a deformação não coaxial por bolsões sigmoidais e grandes cristais de plagioclásio. Muitos dos bolsões quartzo-feldspático apresentam biotita nas bordas. Granada e cianita são abundantes e os cristais são maiores que em IC-01, com até 2 cm, ocorrem na matriz da rocha. A muscovita apresenta menor proporção modal, subordinada as bandas com textura lepidoblástica, em que é concentrada paralela ou sub-paralela à foliação, na forma de porfiroblastos grossos, que podem ser tardios, dada a granulação, até 5 cm, e sua orientação levemente discordante.

Os veios de quartzo apresentam contato retilíneo com a encaixante, enquanto aqueles quartzo-feldspáticos, bem como as acumulações lenticulares de mesma composição, exibem contatos transicionais com a matriz. Neste caso, filmes milimétricos de biotita (até 5 mm), além de cristais de cianita e granada, podem se associar às bordas destas estruturas, envelopando-as. Estas porções estão dispersas na rocha de forma aleatória (Figura 17), formando veios, bolsões e/ou lentes de um a oito centímetros de espessura, contínuos ou descontínuos, com 1 a 50 centímetros de comprimento, paralelos à foliação. Em alguns casos, a presença de cristais de plagioclásio de 1 a 2 cm nas bordas dos veios de quartzo indicam o aproveitamento destes para a nucleação dos veios/bolsões quartzo-feldspáticos. Estas feições se enquadram no tipo descrito por Sawyer (2008) como *patch migmatite*, ou migmatito incipiente, correspondente a rochas que alcançaram o início das condições de anatexia, gerando leucossoma *in situ*.

Na porção inferior da pedreira ocorre gnaiss fino pobre em muscovita e rico em quartzo, com presença de cianita e granada, e estrutura definida por bandamento composicional fino. A textura é lepidogranoblástica, definida pela orientação de biotita, e a composição mais rica em quartzo é diferente da rocha que predomina na pedreira. Veios quartzo-feldspáticos, com espessura máxima de 3 cm, são paralelos à xistosidade, comportando cristais de feldspato com até 5 cm.

Figura 17 - Distribuição do leucossoma quartzo-feldspático em blocos do patamar superior metatexitico (à esquerda) e inferior xistoso (à direita) da pedreira IC03.

Dez exemplares foram selecionados para petrografia e podem ser definidos em quatro grupos: 1) metatexitito com leucossoma e matriz segregados (IC-03-I2, IC-03-K2, e IC-03-L2); 2) xisto homogêneo interpretado como paleossoma (IC-03-H2); 3) metatexitito homogêneo (IC-03-A2, IC-03-D2, e IC-03-F2); e 4) metatexitito com segregações locais de leucossoma (IC-03-B5, IC-03-C7, IC-03-E3, e IC-03-J2). Todos os exemplares apresentam foliação anastomosada, definida por pares S-C, que são marcados pela orientação de micas e domínios de quartzo + plagioclásio, e cristais sigmoidais de plagioclásio. Isso gera a alternância de bandas com textura granoblástica e lâminas de textuta lepidoblástica, dominada por biotita, mas com granada e cianita associadas.

No paleossoma a distribuição do plagioclásio é homogênea e os cristais acompanham a foliação anastomosada, na forma de grãos sigmoides, com cristais tipo “fish”. São minerais bem formados e embora estejam majoritariamente deformados, localmente ocorrem cristais em continuidade óptica com aspecto ígneo e zonação (IC-03-A2, IC-03-I2, IC-03-L2, Figura 18), concêntrica ou não, bordas recrystalizadas e contatos irregulares, podendo apresentar pequenos ângulos diedrais.

O leucossoma se apresenta na forma de lentes em contatos transicionais com o paleossoma, na forma de bolsões com maior volume de segregação e veios quartzofeldspáticos que estão na fonte, mas não necessariamente *in situ*. É composto por megacristais de plagioclásio soldados por quartzo intersticial (IC-03-K2, Figura 18), que pode ser localmente subordinado em volume, ocorrendo tanto na matriz envolvendo os grãos de plagioclásio, bem como inclusões gótulares nos mesmos. Lâminas de biotita envelopam o leucossoma e apresentam deformação concordante com a observada

na matriz. A ampla ocorrência de bolsões e veios de leucossoma sugere o alcance de condições para remobilização local do líquido gerado, a despeito taxa de fusão relativamente baixa (menor que 30%), pelas altas taxas de deformação a que estas rochas foram submetidas, proporcionando a migração e concentração do líquido em sítios preferenciais.

As amostras de metatexito homogêneo são compostas por plagioclásio (25-45%), quartzo (20%), biotita (20-30%), granada (10-15%), muscovita (2-5%) e cianita (2-5%), além de rutilo, ilmenita, zircão, rutilo, apatita, monazita e turmalina como minerais acessórios, além de diminutos cristais de sillimanita intersticiais nas porções granoblásticas. Embora a mineralogia seja semelhante a das rochas observadas em IC-01, as relações estruturais apresentadas, em conjunto com o aumento da granulação, diminuição da muscovita e aumento na quantidade de quartzo, feldspato e biotita, permitem considerar a intensificação e ampla extensão do processo anatético. A quebra de muscovita gera então o cianita-granada-muscovita-biotita-quartzo-plagioclásio metatexito, com leucossoma quartzo-feldspático e melanossoma de biotita, com cianita e granada associadas.

Figura 18 - Feições de fusão em IC-03: cristais de plagioclásio zonado e em continuidade óptica na matriz (A2, L2); plagioclásio ígneo com quartzo associado (E3), megacristais de plagioclásio na matriz (I2); leucossoma thronjemitico-tonalítico na fonte, com quartzo intersticial apresentando pequeno ângulo diedral (J2); e aglomerado de plagioclásios ígneos com quartzo soldando os contatos (K2).

IC07 – Pedreira Souza Dias, Três Corações, MG

Pedreira abandonada cerca de dois quilômetros a leste da pedreira IC-03. Hoje desativada, pertence ao Sr. Lelé, morador de Cambuquira que gentilmente permitiu o franco acesso à mesma. A Figura 19 abaixo apresenta a visão panorâmica da pedreira, num corte leste-oeste.

Figura 19 - Imagem panorâmica da pedreira IC07, em corte E-W, com indicações dos diferentes patamares de exposição.

De forma geral a rocha é mais escura que a IC03 devido a bancos xistosos com maior quantidade de biotita (resíduo/paleossoma?). Possui granulação fina a média e composição dada por cianita, granada, biotita, plagioclásio, quartzo e muscovita, além de ilmenita, apatita e localmente turmalina. Intercalados aos bancos xistosos ocorrem bandas metatexiticas de granulação grossa com mais quartzo e plagioclásio e com presença de muscovita porfiroblástica contida na foliação (Figura 20.a).

No patamar superior da pedreira (cota 1051m), local de coleta da amostra IC-07C, a rocha exposta trata-se de cianita-plagioclásio-granada-biotita xisto com lentes centimétricas de quartzo grosso paralelas a Sn. Na borda das lentes de quartzo são frequentes *spots* centimétricos de composição tonalítica com biotitas euédricas porfiroblásticas (Figura 20.b). Lentes tonalíticas subcentimétricas a centimétricas ocorrem também isolados em veios de quartzo (Figura 20.c), em meio a níveis mais micáceos e com granadas maiores, sendo que os níveis mais granoblásticos possuem granadas de tamanho constante (~0,4cm) e presença porfiroclastos de plagioclásio isolados. Estas pequenas acumulações tonalíticas são consideradas leucossomas *in situ*.

A foliação principal é milonítica recrystalizada, anastomosada, plano axial de dobras recumbentes intrafoliais (Figura 20.d), com sigmoides de quartzo, definida facilmente pela superfície das lentes de quartzo e também por planos de biotita e planos

delgados de 1 a 2 mm de espessura, com muscovitas porfiroblásticas (algumas chegando a 5 cm). São comuns bolsões e/ou veios tonalíticos, de espessura de 1 a 10 cm e comprimento de 5 a 20 cm, concordantes ou inclinados em relação à estrutura principal, interpretados como leucossoma *in source*. Ainda no patamar superior, ocorre dobramento isoclinal recumbente (Figura 21), de plano axial paralelo a estrutura principal S_2 (rumo de mergulho 068/10; $Lb = 166/05$), com deformação concentrada no flanco inferior. Um pouco mais abaixo, na base do paredão principal da pedreira, a foliação é marcada por lentes menores de quartzo grosso, com atitude 124/05.

No paredão principal os níveis granoblásticos perfazem cerca de 50% da exposição, separados por níveis com frequentes veios de quartzo, lentes de composição tonalítica (leucossoma) e bastante biotita. Na base do paredão, ocorre nível xistoso com megacrístais de apatita verde de até 5cm³ (Figura 22). No patamar inferior (Figuras 23), ocorre alternância de níveis xistosos com níveis de metatexito, sendo mais frequentes os veios e bolsões de leucossoma tonalítico com espessura média de 2 cm (Figura 23.a). Neste patamar o domínio superior é composto por cianita-granada-biotita xisto homogêneo de granulação fina e textura granoblástica e ocorrem bandas de metatexito rico em leucossoma com até 5 cm de espessura; mais abaixo, observa-se contraste de competência com alternância de bandas de até 80 cm de xisto fino com bandas da mesma espessura de metatexito. Localmente pode-se reconhecer a continuidade das acumulações tonalíticas engajadas na estrutura principal, com acúmulo de biotita no contato destas estruturas com a matriz xistosa (Figura 23.b), podendo estar também dobradas assimetricamente, truncando a foliação (Figuras 23.a, 23.c e 23.d).

Figura 20.a - porfiroblastos de muscovita sobre os planos de foliação.

Figura 20.b - Plagioclásio associado a borda de veio de quartzo, em meio a nível granoblástico "homogêneo".

Figura 23.c – Nivel de metatexito com bolsão de tonalito paralelo a foliação principal e dobrado assimetricamente.

Figura 23.d.- Bolsões irregulares de leucotonalito.

Ao microscópio, as amostras de IC07 possuem granulação média e semelhantemente àquelas de IC03 apresentam alternância entre bandas granoblásticas quartzo-feldspáticas e bandas xistosas lepidoblásticas definidas por biotita, sendo a composição média dada por 35% de plagioclásio, 30% de quartzo, 20% de biotita, 5% de granada, 1% de cianita, 1% de muscovita e ~1 de outras fases acessórias. O aumento na quantidade e granulação de quartzo e plagioclásio resultam em maior segregação

destas fases em relação à matriz xistosa, alternando bandas granoblásticas cada vez mais espessas, que passam da ordem dos 3 mm nas amostras mais homogêneas até 20 mm nos exemplares mais diferenciados.

As porções xistosas são definidas pela orientação de biotita com quartzo e plagioclásio estirados associados, localmente definindo zonas lepidogranoblásticas nas quais quartzo ou plagioclásio pode ser a fase dominante. A estrutura principal nestes sítios é anastomosada, com pares SC, muitas vezes com desenvolvimento de bandas extensionais de cisalhamento C', *fishes* de mica e plagioclásio, *ribbons* de quartzo e segregações quartzo-feldspáticas sigmoidais (Figura 24). Nas bandas granoblásticas, a predominância de quartzo ou plagioclásio varia, com o plagioclásio ocorrendo na forma de grandes cristais subédricos e aglomerações de cristais menores em contatos soldados, semelhantes a bolsões cumuláticos; enquanto o quartzo ocorre na forma de grandes cristais anédricos, cristais menores recristalizados na forma de *ribbons*, subgrãos intersticiais ou inclusões em formas arredondadas (Figura 25).

Figura 24 - Domínios xistosos de IC07: textura lepidogranoblástica definida pela orientação de biotita em placas bem definidas, plagioclásio na forma de cristais de até 0,5 mm com bordas serrilhadas e subordinadamente quartzo, orientados segundo foliação anastomosada (IC07C); bandamento desenvolvido pela segregação da estrutura entre banda lepidoblástica definida por biotita e bandas granoblásticas definidas por *ribbons* de quartzo e cristais de plagioclásio de até 0,5 mm, também estirados (IC07B'); e subdomínio granoblástico de plagioclásio com contatos mais contínuos, sinuosos, quartzo e biotita decussada intersticiais (IC07D).

Figura 25 - Domínios granoblásticos de IC07: predominância de cristais de plagioclásio com até 1 mm de espessura, com bordas irregulares, interlobadas, e inclusões arredondadas de quartzo, que também pode ocorrer como cristais intersticiais ou subgrãos em bordas de grandes cristais de plagioclásio (IC07B, B'); predomínio de quartzo na forma de *ribbons* com biotita decussada e pequenos cristais de plagioclásio subédrico (IC07C); domínio com quartzo e plagioclásio na forma de grandes cristais estirados (IC07D); e domínio de plagioclásio de diversos tamanhos, subédricos, com contatos caracterizados pela presença de filmes ou acumulações intergranulares alteradas para carbonato (Cb), em contraste com banda de domínio quartzoso (IC07F1).

As granadas de IC07 apresentam, em geral, núcleo poiquiloblástico no qual predominam inclusões de plagioclásio subédrico a anédrico, muitas vezes com extinção concêntrica, além de quartzo subordinado, inclusões locais de biotita e rutilo, e diminutas inclusões de monazita e zircão. Tais inclusões apresentam orientação inter-sin-cinemática em relação à estrutura principal da rocha, enquanto as bordas dos porfiroblastos são em geral límpidas, sobrecrecidas às zonas lepidoblásticas definidas por biotita.

A evolução de litotipos homoganeamente xistosos para rochas com bandamento cada vez mais desenvolvido, alternando porções xistosas e metatexíticas, com acúmulo de leucossoma em quantidades e estruturas variadas, é recorrente em todas as pedreiras. Comparativamente, nota-se que apesar da similaridade composicional entre IC01, IC03 e IC07, há aumento respectivamente progressivo na quantidade de fusão reconhecida, acompanhada pelo aumento de granulação e desenvolvimento de bandamento composicional dos litotipos (Figuras 25). Nota-se que nas amostras mais afetadas pela fusão a proporção de plagioclásio e quartzo são próximas, enquanto as porções menos fundidas mostram predomínio do plagioclásio.

O aumento na quantidade de quartzo e plagioclásio, as feições cumuláticas e variação no hábito deste último em diversas amostras, o aumento progressivo da

granulação e o desenvolvimento de estrutura bandada associado a estas feições são interpretados como evidências da fusão. Embora as porções mais xistosas das rochas relacionadas à unidade Santo Antônio possam sugerir caráter mais residual em comparação àquelas com maior volume de fusão, sobretudo nas porções em que há segregação do leucossoma, é difícil distinguir nestes sítios as porções neoformadas daquelas oriundas da rocha metamórfica pré anatexia. Assim, estas porções, muitas vezes designadas nas descrições como matriz, são consideradas como paleossoma – rocha pouco afetada pela fusão, na nomenclatura de Mehnert (1968). O bandamento alternando camadas xistosas e metatexíticas sugere que a fusão ocorreu em camadas ligeiramente mais férteis em termos composicionais, o que reforça a interpretação das bandas xistosas mais como paleossoma que resíduo verdadeiro do processo anatético aqui representado.

Capítulo III – Geoquímica

Química de rocha total

Para avaliação das diferenças composicionais entre os litotipos das pedreiras IC01, IC03 e IC07 foram obtidas análises de rocha total por Fluorescência de Raios X para elementos maiores, menores e alguns elementos traço, e ICP-MS (*Inductively coupled plasma mass spectrometry*) para elementos traço, incluindo os elementos terras-raras. Foram selecionadas amostras de cianita-granada-biotita-quartzo-plagioclásio xisto homogêneo das três pedreiras, cianita-granada-biotita-quartzo-plagioclásio metatexito de IC03 e IC07 e três amostras de leucossoma de IC03.

Em gráfico binário, a distribuição de elementos maiores *versus* sílica (Figura 26) indica empobrecimento progressivo em Al_2O_3 , Fe_2O_3 , MnO , MgO e K_2O do xisto de IC01 para xistos e metatexitos de IC03 e IC07, respectivamente, além de amostras do leucossoma de IC03 ainda mais empobrecidas nestes óxidos. Nota-se, em contrapartida, o aumento de SiO_2 , Na_2O e CaO nas amostras de IC07 em relação às de IC01 e IC03, e nos exemplares de leucossoma de IC03, que apresentam as maiores quantidades destes componentes. Embora apresentem composição próxima, xisto e metatexito de IC03 e IC07 diferenciam-se pelo maior conteúdo de cálcio no primeiro; entre as amostras de xisto nota-se ainda o enriquecimento de cálcio em IC03 e IC07 em comparação a IC01. Estas relações refletem o aumento das quantidades de quartzo e plagioclásio em IC03 e IC07 em detrimento de micas, granada e cianita, presentes em maior quantidade em

IC01. A menor quantidade de cálcio e quantidade ligeiramente maior de sódio no metatexito em relação ao xisto pode indicar mudança composicional nos grãos de plagioclásio presentes nos referidos litotipos, predominando membros sódicos no metatexito e cálcicos no xisto, o que é compatível com as grandes quantidades de sódio observadas nos veios de leucossoma, chegando a quantidades próximas de 6% em proporção molar. A presença de até 1% de TiO_2 no xisto e metatexito reflete a presença de rutilo, como inclusões em granada e cianita ou na matriz destas rochas, e a diminuição do óxido no leucossoma sugere a estabilidade da fase no processo anatético, sem que ocorra sua dissolução e posterior reprecipitação, concentrando o mineral no resíduo ou paleossoma.

Em relação aos elementos menores e traço, também plotados contra sílica, (Figuras 27) observa-se empobrecimento progressivo tanto das fases xistosas para metatextos e leucossoma, respectivamente, como de IC01 para IC03 e IC07, respectivamente, nos teores de Ba, Ni, B, V, Ga, Zr, Pb, Y, Zn e Rb, interpretado como retenção sobretudo de biotita nas amostras menos diferenciadas. O aumento de Sr nas rochas de IC03 e IC07, no metatexito e leucossoma, é compatível com o aumento da quantidade de plagioclásio, enquanto o empobrecimento em elementos como Zr, Hf, Th podem indicar a retenção de fases acessórias como monazita e zircão nas porções menos afetadas por fusão ou o não alcance de condições que permitissem a dissolução e reprecipitação destas fases (Figura 28).

Figura 26 - Elementos maiores *versus* sílica em proporção molar nos litotipos de IC01, IC03 e IC07.

Figura 27 - Elementos menores e traço *versus* porcentagem em óxido de sílica para os litotipos de IC01, IC03 e IC07.

Figura 28 - Elementos traço *versus* porcentagem em óxido de sílica para os litotipos de IC01, IC03 e IC07.

A distribuição de elementos terras raras é apresentada na forma de *spidergrams* normalizados a condrito, manto primitivo e também por uma amostra de xisto homogêneo de IC01, para análise da diferenciação entre os distintos litotipos de IC01, IC03 e IC07 (Figura 29). Em relação ao condrito e manto primitivo, as amostras apresentam enriquecimento com até 100 vezes ETR leves e cerca de 10 vezes ETR pesados para xisto e metatexito, enquanto as amostras de leucossoma apresentam enriquecimento até 10 vezes ETR leves e ETR pesados entre 1 e 10 vezes, ou levemente empobrecidos ao padrão, além de anomalia positiva de európio, indicando o plagioclásio como fase importante nestas amostras. Normalizadas pelo exemplar de xisto de IC01, as demais amostras de xisto e metatexito apresentaram similaridade composicional entre si, o que indica que estes litotipos não tiveram modificações composicionais significantes entre si, como por exemplo a dissolução e reprecipitação das fases acessórias, que em geral retêm os ETR. Esta interpretação é compatível com o empobrecimento destes elementos nas amostras de leucossoma, cuja anomalia positiva de európio sugere o plagioclásio como fase principal da fusão.

Estas características indicam que a fusão ocorreu em condições *P-T* relativamente moderadas (ver Capítulo IV, Metamorfismo e Fusão), e insuficientes para o desenvolvimento de volume de segregação composicional que possibilitasse a

diferença química entre os dois, xisto e metatexito. A dissolução e reprecipitação de fases acessórias refratárias no leucossoma foi insignificante, dada as baixas taxas de fusão implicadas pela química de rocha, o que é refletido nos padrões de ETR, totalmente empobrecidos, com exceção de európio.

Figura 29 - ICP-MS: distribuição de elementos terras raras normalizados a condrito, manto primitivo (Mcdonough & Sun, 1995) e IC01E3 (xisto homogêneo).

Química mineral

Para análise das mudanças composicionais que caracterizam a evolução metamórfica das rochas investigadas, obteve-se a química mineral de cristais de plagioclásio, granada, biotita e muscovita em diversos sítios texturais das amostras de IC01, IC03 e IC07. Nos cristais de plagioclásio e granada as análises foram executadas na forma de perfis ao longo borda-núcleo-borda, buscando ressaltar eventuais variações composicionais registradas ao longo do crescimento dos minerais, enquanto nas micas apenas o par núcleo-borda, quando não somente o núcleo, foram analisados. A adoção deste método consiste no fato de que granada e plagioclásio podem apresentar várias fases de (sobre)crescimento, o que potencializa o isolamento e preservação de núcleos reliquiais, sobretudo na granada, enquanto as micas são facilmente reequilibradas quimicamente a cada etapa do metamorfismo (Spear, 1993).

A variação no teor de anortita no plagioclásio, dos membros finais almandina, piropo, grossulária, espessartita e andradita na granada, e as relações entre Fe e Mg, Al e Si e Na e K nas micas foram os parâmetros utilizados para a avaliação da química dos cristais. De forma geral, os cristais de plagioclásio são ricos em albita, mas podem alcançar composição com teor de anortita de até 48%. A granada é rica na molécula de almandina; biotita apresenta composição típica, com $X_{Mg} < 0,66$ e $0,33 < Al/Si < 0,8$. Muscovita tem ampla solução sólida com paragonita, apresentando até 10% de Na_2O nas amostras de IC03. A Figura 30 apresenta o diagrama ACF com as composições de plagioclásio, granada e biotita obtidas nas amostras das diferentes pedreiras. As seções a seguir apresentam a caracterização completa de cada um dos minerais analisados.

Figura 30 - Diagrama ACF apresentando as composições de plagioclásio (hachura com linhas verticais), granada (hachura com linhas inclinadas) e biotita (hachura quadriculada) nas amostras de IC01 (vermelho), IC03 (azul) e IC07 (verde).

Plagioclásio

Para análise da variação composicional do plagioclásio, foram realizados perfis composicionais em cristais de três sítios texturais diferentes das amostras das pedreiras IC01, IC03 e IC07: matriz (paleossoma/resíduo), leucossoma, e inclusões em granada. Foram analisados 475 pontos em 67 cristais pertencentes à matriz; 263 pontos em 35 cristais do leucossoma e 147 pontos em 29 cristais inclusos em granada, totalizando 894 análises em 137 cristais de plagioclásio (vide anexo 2). O número de pontos em cada perfil variou, de acordo com o cristal em questão e seu sítio textural, entre 3 e 24 análises. Em cristais diminutos, apenas o par núcleo-borda ou a composição do núcleo foram obtidas.

Em amostras da pedreira IC-01, 118 análises foram obtidas em 24 cristais de três amostras: IC01C2, caracterizada pela predominância de veios de quartzo entre os quais se intercalam bandas de espessura centimétrica de matriz homogênea granoblástica; IC01D2, bandamento composicional em escala milimétrica e veio de quartzo paralelizado à estrutura principal; e IC01E3, de estrutura homogênea e textura granoblástica, com concentração local de *ribbons* granoblásticos compostos por quartzo com plagioclásio subordinado. Devido a associação de plagioclásio de aspecto ígneo associado às bordas ou mesmo internos às estruturas de veios e *ribbons* de quartzo, estes

sítios foram interpretados como protoleucossomas. Assim, foram analisados 71 pontos em 15 cristais da matriz, 27 pontos em 5 cristais no leucossoma, e 10 análises em um cristal incluído em granada.

Os cristais da matriz são idioblásticos, com bordas retilíneas bem definidas e geminação ora conspícua, ora ausente, com extinção inclinada, ondulante ou concêntrica, localmente com sinais de recristalização dinâmica marcada por contatos interlobados com assimilação de quartzo através de migração de bordas e *bulging*. Ocorrem também cristais subidioblásticos a xenomórficos, com bordas recristalizadas em torno de núcleos idioblásticos, com marcante extinção diferencial, em geral ondulante a concêntrica, evidenciando fases distintas de crescimento do mineral.

A variação do teor de anortita nos cristais de plagioclásio da matriz de IC01 pode ser vista nos perfis composicionais apresentados na Figura 31: destacam-se dois grupos composicionais maiores, onde se diferenciam os cristais relacionados à amostra IC01D2, com teor de anortita variando entre An_{32} e An_{44} para os cristais relacionados às mais ricas em biotita, com variação errática na extensão borda-núcleo-borda. O segundo grupo é composto pelos cristais das amostras IC01C2 e IC01E3, cujos teores de anortita variam entre An_{20} e An_{32} , sendo que os cristais de IC01C2, rocha rica em veios de quartzo, apresentam os cristais mais albiticos. Embora localmente possa ser reconhecido algum padrão de variação do teor de anortita relacionando estágios de crescimento de núcleo e bordas (e.g. IC01E3-C1PLAG2, Figura 31), há forte sobreposição composicional dos pontos analisados em cada amostra, tornando difícil a interpretação destas variações.

Figura 31 - Perfis composicionais em cristais de plagioclásio na matriz de IC01: teor de anortita *versus* número de análises. Amostras: IC01C2 (azul, linha pontilhada), IC01D2 (vermelho, linha tracejada) e IC01E3 (laranja, linha cheia). Destaque para o enriquecimento em anortita nos cristais pertencentes à matriz com bandamento composicional (IC01D2) e compatibilidade composicional entre os cristais de matriz homogênea de IC01C2 e IC01E3, a primeira apresentando os cristais mais albiticos.

Relacionados aos veios e *ribbons* de quartzo, interpretados como protoleucossomas, cinco cristais de plagioclásio das amostras IC01C2 e IC01E3 foram analisados. São cristais e megacristais xenomórficos a subidioblásticos, com extinção ondulante a concêntrica, geralmente saussuritizados e com bordas recrystalizadas. Estes minerais variam entre An_{13} e An_{31} , e podem apresentar zonação com núcleos mais ricos na molécula de anortita (e.g. IC01C2-C6PLG), sendo os cristais relacionados à IC01E3 os mais ricos em anortita, variando entre An_{24} e An_{31} (Figura 32). Uma inclusão euédrica de plagioclásio em granada foi analisada (Figura 33), apresentando zonação com núcleo de composição An_{40} e bordas mais ricas em Na_2O , com composição variando entre An_{38} e An_{30} (Figura 33).

Figura 32 - Perfis composicionais em cristais de plagioclásio em *ribbons* e veios de IC01: teor de anortita *versus* número de análises – composições albíticas para IC01C2 (linha pontilhada) em relação a IC01E3 (linha cheia). Destaque para a conspícua zonização núcleo-borda presente em todos os cristais analisados.

Figura 33 - Perfil composicional em inclusão de plagioclásio em granada de IC01E3: teor de anortita *versus* número de análises – núcleo anortítico em contraste com bordas mais albíticas.

Para a pedreira IC-03, quatro amostras foram selecionadas: IC03B5, IC03E3 e IC03J2, compostas por matriz metatextítica com porção de leucossoma segregado; e IC03F2, metatextito homogêneo, sem grandes segregações. 331 análises foram executadas em 41 cristais de plagioclásio em distintos sítios texturais: 223 pontos em 25 grãos da matriz, dos quais 3 tiveram somente o núcleo analisado; 79 análises em 8

cristais de leucossoma; e 30 pontos em 7 cristais inclusos em granada. Na matriz, foram analisados megacristais subidioblásticos a sigmoidais/arredondados, com extinção ondulante a concêntrica, com ou sem geminação, muitas vezes com inclusões goticulares de quartzo, e cristais menores, subidioblásticos, com ou sem geminação aparente, extinção variando entre inclinada, ondulante e concêntrica, e comumente deformados segundo a foliação principal. Neste sítio textural o teor de anortita varia entre An_{15} e An_{35} (Figura 34), com dois grupos composicionais destacados: um com maior teor de anortita (An_{27} a An_{31}), representado por cristais das amostras IC03F2 e IC03J2; e o grupo de menor teor de anortita (An_{15} a An_{26}), que abrange a maioria dos cristais analisados. Embora os *ranges* composicionais apresentem sobreposição, é possível reconhecer cristais com núcleo albítico e bordas anortíticas (e.g. IC03E3-C1PL); e cristais nos quais a variação composicional não representa zonação núcleo-borda específica.

Os cristais de plagioclásio associados ao leucossoma das amostras de IC03 (Figura 35) podem ocorrer como megacristais idioblásticos a subidioblásticos, em geral saussuritizados e com inclusões de quartzo, ou como cristais menores, idioblásticos, menos alterados. O teor de anortita nestes cristais varia entre An_{19} e An_{31} , sendo os cristais da amostra IC03J2 os mais ricos em anortita, An_{23} a An_{31} , enquanto um cristal da amostra IC03F2 apresenta a composição mais rica em albita, An_{19} , em contraste com bordas mais cálcicas, An_{22-23} . Com exceção deste, os demais cristais analisados não apresentam contraste bem definido entre os teores de anortita de núcleo e borda. As inclusões de plagioclásio em porfiroblastos de granada das amostras de IC03 (Figura 36) ocorrem como pequenos cristais idioblásticos a xenomórficos, com teor de anortita variando entre An_{24} e An_{36} , podendo-se reconhecer sutil enriquecimento das bordas de alguns cristais em anortita (e.g. IC03J2-C3PLINCLGRT2).

Figura 34 - IC03: cristais de plagioclásio da matriz. IC03B5 (laranja, linha cheia), IC03E3 (roxo, linha pontilhada), IC03F2 (azul, linha tracejada), e IC03J2 (vermelho, linha traço-ponto).

Figura 35 - Perfis composicionais em cristais de plagioclásio do leucossoma de IC03: teor de anortita *versus* número de análises. Amostras: 03B5 (roxo, linha pontilhada), 03E3 (azul, linha cheia), 03F2 (vermelho, linha tracejada), 03J2 (verde, linha com contorno).

Figura 36 - Perfis composicionais de plagioclásio incluído em granadas de IC03: teor de anortita *versus* número de análises. Amostras: 03B5 (linha pontilhada), 03E3 (linha cheia), 03F2 (linha tracejada), 03J2 (linha com contorno).

As amostras de IC07 apresentam bandamento composicional mais desenvolvido, alternando bandas de leucossoma e matriz com espessura de até 1 cm, embora localmente ocorram porções mais espessas de leucossoma segregado. Desta pedreira foram obtidas 445 análises em 72 cristais de plagioclásio, sendo 181 pontos em 27 cristais da matriz; 157 pontos em 22 cristais do leucossoma; e 107 análises em 21 inclusões nos porfiroblastos de granada. Na matriz, o plagioclásio apresenta granulação média (~0,5 mm), distribuição homogênea, hábito subidioblástico, em geral estirado e deformado segundo a estrutura principal, com ou sem geminação aparente, ângulo de extinção variável. Ao contrário de IC01 e IC03, todos os cristais agrupam-se no intervalo de teor de anortita entre An_{27} e An_{34} e embora haja sobreposição nos *ranges* composicionais observados, distinguem-se cristais de núcleo anortítico com bordas albíticas (e.g. PLA1_IC07E_C2); núcleos albíticos com bordas anortíticas (e.g. PLA5_IC07C_C2); e cristais nos quais a variação do teor de anortita não representa um padrão núcleo-borda específico (Figura 37).

No leucossoma, os cristais de plagioclásio apresentam-se como megacristais subidioblásticos, com extinção ondulante a concêntrica, com ou sem geminação aparente, pouco saussuritizados; ou como cristais menores, subidioblásticos a xenomórficos, com extinção ondulante a concêntrica, com ou sem geminação, sem saussuritização. O teor de anortita nestes cristais (Figura 38) varia entre An_{26} e An_{34} , coexistindo cristais com núcleo albítico e bordas anortíticas (e.g. PLA4_IC07E_C4); núcleos anortíticos com bordas albíticas (e.g. PLA3_IC07D); e cristais nos quais a variação composicional não reflete zonação núcleo-borda específica. Em relação às inclusões de plagioclásio em porfiroblastos de granada de IC07, em geral na forma de pequenos cristais idioblásticos, com ou sem geminação, podendo ocorrer também formas subidioblásticas a xenomórficas, as mesmas variações composicionais são observadas (Figura 39): núcleos anortíticos com bordas albíticas (e.g. PLA1_IC07C_C1); núcleos albíticos com bordas anortíticas (e.g. PLA4_IC07E_C2); e predominantemente cristais cuja variação composicional não reflete especificamente zonação núcleo-borda.

Figura 37 - Perfis composicionais em cristais de plagioclásio da matriz de IC07: teor de anortita *versus* número de análises. Núcleos albíticos com bordas anortíticas em vermelho sangue; núcleos albíticos com bordas anortíticas em vermelho escuro; e variação composicional sem padrão núcleo-borda específico em vermelho claro. Atentar para variação núcleo anortítico – borda interna albítica – borda externa anortítica (PLA6_IC07D_C4, em marrom claro) – reflexo de precipitação de fundido seguido de recristalização metamórfica das bordas? Amostras: 07A (linha com contorno), 07C (linha cheia), 07D (tracejado com contorno), 07E (linha traço-pontuada).

Figura 38 - Perfis composicionais de cristais de plagioclásio no leucossoma de IC07: teor de anortita *versus* número de análises. Núcleos albíticos com bordas anortíticas em azul escuro; núcleos albíticos com bordas anortíticas em azul claro; cristais com zonação núcleo-borda interna-borda externa em roxo; cristais sem zonação específica em azul médio. Amostras: 07A (linha com contorno), 07C (linha pontilhada), 07D (linha cheia), 07E (linha tracejada).

Figura 39 - Perfis composicionais em cristais de plagioclásio inclusos em porfiroblastos de granada de IC07: teor de anortita *versus* número de análises. Núcleos anortíticos com bordas albíticas em laranja escuro; núcleos albíticos com bordas anortíticas em laranja médio; cristais com zonação núcleo-borda interna-borda externa em marrom; cristais sem zonação específica em laranja claro. Amostras: 07^a (linha pontilhada), 07C (linha cheia), 07D (linha tracejada), 07E (linha com contorno).

As Figuras 40 a 42 apresentam a dispersão das composições de núcleo e borda de cristais de plagioclásio relacionados à matriz, leucossoma e inclusões de granada das amostras de cada uma das pedreiras pedreiras, IC01, IC03 e IC07. As amostras de IC01 apresentam variação composicional entre An_{17} e An_{41} , com cristais inclusos em granada variando entre An_{30} e An_{41} , da matriz entre An_{22} e An_{41} e os do leucossoma entre An_{16} e An_{31} , ou seja, progressivamente mais ricos na molécula de albita, respectivamente (Figura 40). Em IC03, a variação composicional está entre An_{21} e An_{36} , mas com maior homogeneidade na composição de cristais da matriz e do leucossoma entre An_{20} e An_{30} , sendo dos cristais inclusos em granada os maiores valores de anortita, An_{24-36} (Figura 41). Nas amostras de IC07 a composição dos distintos sítios texturais mostra-se mais homogênea, com cristais de matriz entre An_{28} e An_{34} ; An_{26} a An_{33} para os cristais do leucossoma; e os extremos composicionais observados nas inclusões de granada, que variam entre An_{16} e An_{47} (Figura 42).

A comparação entre as variações da composição de cristais de plagioclásio em sítios texturais análogos de amostras das diferentes pedreiras é apresentada nas Figuras 43, 44 e 45. Em relação aos cristais da matriz o intervalo composicional varia entre An_{17} e An_{39} , sendo que nas amostras de IC01 ocorrem os cristais com composições mais ricas em cálcio, An_{20} a An_{39} ; nas de IC03 as mais ricas em Na, An_{17-35} , e IC07 a composição intermediária, An_{28-34} (Figura 43). Nos cristais de plagioclásio do leucossoma, as amostras de IC01 apresentam as composições mais ricas em albita, An_{13-31} , e IC03 apresenta composição é intermediária entre a primeira e IC07, com as respectivas variações An_{19-31} e An_{26-34} (Figura 44). Nas inclusões em granada observa-se sobreposição composicional entre as amostras, com IC07 abrangendo os extremos composicionais ricos em sódio e cálcio, An_{20-47} , enquanto nas outras amostras as composições estão abrangidas dentro desse intervalo, com IC01 variando entre An_{31} e An_{40} e IC03 entre An_{24} e An_{36} (Figura 45).

A Figura 46 apresenta a variação de todas as análises obtidas em cristais da matriz, leucossoma e inclusões em granada de IC01, IC03 e IC07, definindo intervalo composicional contínuo entre An_{16} e An_{47} , no qual os cristais com composição mais ricos em albita ocorrem na matriz e leucossoma de IC01 e IC03 (An_{16-26}). Os cristais mais ricos em anortita estão relacionados à matriz de IC01 e inclusões de IC01 e IC07 (An_{16-26}); enquanto as composições intermediárias pertencem aos cristais da matriz e leucossoma de IC07, e das inclusões de IC03 e IC07.

Figura 40 - Dispersão das composições de núcleo e borda em cristais de plagioclásio de IC01: em vermelho cristais da matriz; azul para cristais do leucossoma; e laranja para cristais inclusos em granada.

Figura 41 - Dispersão das composições de núcleo e borda em cristais de plagioclásio de IC03: em vermelho os cristais da matriz; azul para cristais do leucossoma; e laranja para cristais inclusos em granada.

Figura 42- Dispersão das composições de núcleo e borda em cristais de plagioclásio de IC07: em vermelho os cristais da matriz; azul para cristais do leucossoma; e laranja para cristais inclusos em granada.

Figura 43 - Variação das composições de núcleo e borda em cristais de plagioclásio da matriz de IC01 (triângulos verdes), IC03 (círculos laranjas) e IC07 (losangos azuis).

Figura 44 - Dispersão das composições de núcleo e borda em cristais de plagioclásio do leucossoma de IC01 (triângulos verdes), IC03 (círculos laranjas) e IC07 (losangos azuis).

Figura 45 - Dispersão das composições de núcleo e borda em cristais de plagioclásio inclusos em granada de IC01 (triângulos verdes), IC03 (círculos laranjas) e IC07 (losangos azuis).

Figura 46 - Dispersão das composições de núcleo e borda em cristais de plagioclásio de IC01 (triângulos), IC03 (círculos) e IC07 (losangos) em diferentes sítios texturais: matriz, em vermelho; leucossoma em azul; e inclusões de granada em laranja.

A variação composicional contínua dos cristais de plagioclásio das amostras dos diferentes sítios texturais analisados em IC01, IC03 e IC07 atesta sua evolução pelo mesmo processo anatético: cristais inclusos em granada mais ricos em anortita; cristais do leucossoma enriquecidos na molécula albíta e cristais da matriz podendo apresentar dois grupos composicionais (IC01 e IC03) registram a geração de líquido sódico, sendo as fases mais anortíticas residuais ou reliquias do que as mais ricas em albíta, enquanto os grupos composicionais da matriz associados à existência de cristais com diferentes padrões de zoneamento núcleo-borda indicam processos de dissolução e reprecipitação nos contatos de plagioclásio da matriz e/ou retenção de fases residuais

neste sítio. A diminuição da discrepância entre as composições de cristais em diferentes sítios texturais nas pedreiras de topo (IC03 e IC07) mostra a extensão de influência da fusão, que começa limitada a veios de quartzo e segregações granoblásticas formando leucossomas *in situ* (IC01) e estende-se de forma penetrativa na rocha formando bolsões ou veios de leucossoma *in situ* ou *in source* (IC03, IC07).

Nos exemplares de IC01, onde há grande quantidade de veios e *ribbons* de quartzo com plagioclásio subordinado, observam-se as primeiras evidências de fusão, formando-se nas porções quartzo-feldspáticas os primeiros cristais de plagioclásio oriundos do líquido neoformado, aqueles mais ricos em albita e em contraste com a matriz em que os cristais são mais ricos em anortita. As rochas em IC03 representam o estágio mais avançado do processo, no qual a fusão é penetrativa, diminuindo o contraste composicional, com segregação de líquido que cristaliza na forma de veios de leucossoma *in situ* ou *in source* com megacristais de plagioclásio. Finalmente, IC07 registra o ápice do processo, com homogeneização composicional atingida provavelmente a partir da penetratividade total da fusão concomitante à evolução do bandamento composicional, e reequilíbrio final favorecido pelo contraste composicional em porções do leucossoma e nos contatos entre granada e inclusões.

Assim, o contraste entre as composições de inclusões, matriz e veios e *ribbons* de IC01 seria o registro do início do processo anatético; a similaridade composicional entre os cristais de leucossoma de IC01 e matriz e leucossoma de IC03 registrariam a evolução da penetratividade da fusão, já com tendência de reequilíbrio; enquanto as composições intermediárias dos cristais de IC07 devem refletir o alcance do reequilíbrio final e recristalização das bordas dos plagioclásios de leucossoma e inclusões. Os cristais inclusos em granada de IC01 devem ser os representantes mais próximos do metamorfismo progressivo original, enquanto aqueles observados nas granadas de IC03 e IC07 já refletem mudanças composicionais relacionadas à fusão. A presença de cristais com zanação núcleo-borda variável entre membros albíticos e anortíticos nos diferentes sítios texturais de IC01, IC03 e IC07 demonstra que os processos de fusão e recristalização foram concomitantes ao longo da evolução destas rochas, embora um ou outro possa ter sido predominante ao longo da trajetória do metamorfismo.

Granada

Vinte e cinco perfis composicionais variando de 3 a 45 pontos foram obtidos em diversos tipos de porfiroblastos de granada nas amostras de IC01, IC03 e IC07: são

cristais com fases de crescimento inter-, sin-, e/ou pós-cinemáticas; ricos em inclusões ou límpidos; predominantemente almandínicos em todas as amostras (Alm₅₅₋₇₂) e, em geral, com forte zonação núcleo-borda. Os perfis composicionais dos cristais analisados são apresentados nas Figuras 47 e 48.

Nas amostras de IC01 foram analisados dois cristais inter- a pós cinemáticos localmente rotacionados, com sombras de pressão pouco desenvolvidas, poucas inclusões, e bordas límpidas crescendo sobre biotita adjacente. Nestes cristais os teores de almandina, piropo, espessartita, grossulária e andradita variam, respectivamente, entre 56 e 62%, 5 e 9%, 2 e 13%, 14 e 22% e ~7%. A zonação núcleo borda é marcada pela variação do par almandina-espessartita, com núcleo e bordas externas enriquecidos em manganês contrastando-se com bordas internas ricas em Fe²⁺. Na amostra IC01C2-C3 (Figura 47) as composições do trio borda-núcleo-borda foram obtidas em um pequeno cristal de granada pós-cinemático sobrecrecido em biotita, relativamente límpido, apresentando apenas diminutas inclusões dispersas aleatoriamente, caracterizado como Alm_{55,5-56}, Py₆₋₈, Sps₂₂₋₂₄, Grs₆₋₈ e And₇. Embora não seja perceptível uma variação composicional considerável, observa-se que o teor do membro magnésiano tem comportamento semelhante ao do membro ferroso, enquanto a grossulária tem discreto aumento em relação à diminuição destes componentes. Na amostra IC01E3-C1 (Figura 47), no qual a granada apresenta núcleo inter- (sin-?) e bordas pós-cinemáticas, o contraste entre grossulária e almandina é conspícuo, alternando núcleo cálcico e bordas ferrosas, com composição Alm₆₀₋₆₄, Py₁₀₋₁₅, Sps₅₋₁₂, Grs₆₋₁₅ e And₇.

As granadas de IC03 podem apresentar até três estágios de crescimento (e.g. 03B5-C10, Figura 47), com núcleos pré-, inter- a sin-cinemáticos, geralmente ricos em inclusões, e bordas mais límpidas sin- a pós-cinemáticas. Estes cristais apresentam composição Alm₅₅₋₇₂, Py₄₋₂₄, Grs₅₋₂₄, Sps₂₋₁₀, e And₇₋₈, ora com zonação núcleo-borda conspícua, ora com variação composicional aleatória ao longo do mineral. Nos cristais com zonação núcleo-borda a variação composicional mostra núcleos depletados e bordas ricas em Fe²⁺; no que se refere às trocas catiônicas observam-se três comportamentos distintos: enriquecimento em Ca e Mn em detrimento de Fe²⁺ e Mg (e.g. 03F2-C7, 03E3-C3 – Figuras 47 e 48), onde a composição é dada por Alm₅₆₋₆₈, Py₄₋₁₉, Grs₆₋₂₄, Sps₂₋₁₀ e And₇₋₈; depleção em Fe²⁺ e Mn com aumento de Ca e Mg (e.g. 03E3-C4, Figura 47), de composição Alm₆₄₋₇₁, Py₁₀₋₁₉, Grs₆₋₈, Sps₂₋₇ e And₇; e aumento de Mg em detrimento ao Fe²⁺, observado na amostra 03B5-C10 de composição Alm₆₄₋

₆₈, Py₁₄₋₂₀, Grs₆₋₇, Sps₃₋₅ e And₇. Para cristais sem zonação núcleo-borda específica observam-se cristais nos quais as trocas catiônicas são marcadas pelo par Fe-Mg (e.g. 03J2-C3, C7; 03B5-C9, Figuras 47 e 48), com composição Alm₆₀₋₇₂, Py₇₋₂₄, Grs₅₋₉, Sps₃₋₅ e And₇; e um cristal no qual observam-se trocas entre os pares Fe-Mn e Ca-Mg, com composição Alm₆₃₋₆₈, Py₁₂₋₁₈, Grs₆₋₁₃, Sps₁₋₇ e And₇.

As granadas de IC07 são em geral sin-cinmáticas, com sombras de pressão ausentes a pouco desenvolvidas, inclusões sem delimitação de estruturas pretéritas e localmente apresentam crescimento em estrutura esquelética. Para avaliação da variação composicional foram realizados perfis núcleo-borda nos cristais bem formados e perfis segmentados em cristais de hábito heterogêneo ou esquelético (e.g. 07A-C3, Figura 48), sendo a composição geral dada por Alm₆₄₋₇₁, Py₁₁₋₁₇, Grs₇₋₁₆, Sps₂₋₅ e And₃₋₇. As trocas catiônicas são marcadas pelo par Fe²⁺-Mg, podendo ocorrer também influência do Ca em alguns cristais (e.g. 07A-C2, Figura 47).

Figura 47 - Perfis composicionais de granada.

Figura 48 - Perfis composicionais de granada.

A análise da dispersão composicional nas granadas de IC01, IC03 e IC07 é apresentada na Figura 49 em função do triângulo Py-Alm+Sps-Grs+And e pelos diagramas Py *versus* Alm+Sps/Grs+And, que destacam as relações apresentadas naquele triângulo. Nestes diagramas observa-se que as amostras de IC03 abrangem o maior *range* composicional, seguida por IC01, enquanto as granadas de IC07 apresentam maior homogeneidade na composição. Os extremos magnesianos são relacionados à IC03, enquanto o máximo e mínimo teores de Alm+Sps são observados nas amostras de IC01. Em relação aos membros grossulária e andradita, as amostras de

IC07 apresentam os menores teores, enquanto a maior porcentagem é observada em cristais de IC03, embora este grupo e o representado pelas amostras de IC01 apresentem amplo *range* composicional com forte sobreposição, principalmente nos membros mais ricos em Grs+And. Nas amostras de IC01, separam-se pelo teor de piropo dois grupos composicionais: o de maior teor, no qual encontram-se os maiores teores de almandina e espessartita, sobretudo nas bordas dos cristais; e o de menor teor, que apresenta as maiores quantidades de grossulária mais andradita, com leve enriquecimento em piropo observado nas bordas. Em IC03 nota-se variação composicional contínua, com leve diferenciação das bordas dos cristais para composições mais ricas em piropo ou almandina, formando um intervalo que sobrepõe as amostras das demais pedreiras. Finalmente, as granadas de IC07 apresentam composição intermediária entre IC01 e IC03, compatível com os exemplares mais magnesianos e menos cálcicos destas pedreiras, e com contraste composicional de núcleo e bordas muito discreto, em geral para membros mais ricos em almandina.

A variação na quantidade de piropo das granadas, aumentando progressivamente dos exemplares de IC01 para IC03 e IC07, reflete o aumento relativo do grau metamórfico da base para o topo e a homogeneidade composicional observada nos cristais de IC07 é compatível com esta interpretação. A presença de porfiroblastos com enriquecimento de Ca, presentes apenas em IC01 e IC03, também podem atestar o metamorfismo progressivo em condições mais brandas de metamorfismo. Por fim, a diminuição na quantidade de cálcio nos membros de maior grau metamórfico deve refletir a transição da assimilação deste elemento pela granada nos estágios de fusão, quando o plagioclásio torna-se mais albitico pela presença do fundido rico em sódio, favorecendo o enriquecimento da granada em grossulária, e o momento de reequilíbrio final com a matriz, após o alcance do *solidus*, com nova troca de Ca com o plagioclásio. Vale ainda ressaltar que o baixo teor relativo de piropo (<25%) observado nas amostras de todas as pedreiras sugere que estas rochas não alcançaram condições superiores à fácies anfibolito, já que rochas de alto grau costumam apresentar entre 40 e 70% deste componente (Deer *et al.*, 1966).

Figura 49 - Dispersão das composições de granadas de IC01 (vermelho), IC03 (verde) e IC07 (azul). No triângulo Py-Alm+Sps-Grs+And as linhas cheias referem-se à composição interna e as linhas tracejadas à composição das bordas dos minerais.

Biotita

Complementando a caracterização da paragênese principal de IC01, IC03 e IC07, 108 análises foram executadas em 69 micas localizadas em distintos sítios texturais das diversas amostras, sendo 62 análises em 35 cristais de biotita e 46 pontos em 34 exemplares de muscovita. Em IC01 foram analisados 12 cristais de biotita da matriz variando desde pequenos exemplares decussados na matriz granoblástica até cristais envolvidos no envelopamento grandes cristais de plagioclásio ou no desenvolvimento de faixas lepidoblásticas, totalizando 28 análises; e 14 cristais de muscovita, ora pouco desenvolvidas e subordinadas nas porções lepidoblásticas da matriz, ora na forma grandes cristais idioblásticos relacionados às porções granoblásticas com desenvolvimento de leucossoma ou associados a megacristais de plagioclásio, somando 23 análises. Em IC03 foram obtidas as composições de 25 pontos em 14 cristais de biotita na matriz, leucossoma, e também associados a megacristais de plagioclásio e porfiroblastos de granada; além de 15 análises em 12 cristais muscovita nestes mesmos sítios. Não foram obtidas análises de muscovita para as amostras de IC07.

Nas análises de biotita de IC01 observa-se um *trend* composicional contínuo de XMg entre 0,45 e 0,56 e razão Al/Si entre 0,59 e 0,65, no qual as amostras IC01C2, rica em veios; IC01D2, de estrutura microbandada; e IC01E3, de estrutura mais homogênea, são progressivamente mais ricas em magnésio e alumínio, com XMg variando entre 0,45 e 0,49; 0,49 a 0,53; e 0,53 a 0,56, respectivamente. Em IC01C2 e IC01E3 observa-se ainda ligeiro enriquecimento deste elemento nas bordas dos cristais, enquanto em IC01D2 ocorrem bordas tanto enriquecidas quanto empobrecidas em Mg em relação aos respectivos núcleos (Figura 50). Em IC03 o XMg varia entre 0,48 e 0,6, com razão Al/Si entre 0,59 e 0,64, sendo os menores teores de Mg observados em cristais relacionados a borda (XMg=0,48) e inclusão (XMg=0,53) de granada, enquanto o maior teor deste elemento, bem como a maior razão de Al/Si encontram-se em cristais da matriz (XMg=0,6 e Al/Si=0,64, respectivamente), com a maior parte dos dados concentrados entre XMg₅₄₋₅₇ e Al/Si_{0,59-0,61} (Figura 51). Finalmente, a biotita de IC07 apresenta teor de Mg entre 0,56 e 0,62, distinguindo-se os cristais de 07A, que concentram-se em dois grupos: XMg₅₆₋₅₈ Al/Si_{0,57-0,58} e XMg₅₇₋₅₉ Al/Si_{0,53-0,55}; e os cristais de 07C, dos quais duas amostras ocorrem no intervalo XMg₅₇₋₅₉ Al/Si_{0,59-0,6} e uma com XMg₆₂ Al/Si_{0,58} (Figura 52).

A análise da dispersão composicional inter-relacionando as amostras das três pedreiras (Figura 53) mostra os maiores teores de Mg para IC07 (0,56 a 0,62), que apresenta menor razão Al/Si (0,53 a 0,60); enquanto os menores valores de XMg ocorrem em IC01 (0,45 a 0,55), cujas razões Al/Si são mais elevadas (0,59 a 0,65). IC03 apresenta composição intermediária entre IC01 e IC07, com XMg entre 0,48 e 0,60, compatível com as amostras de IC07, mas com razão Al/Si entre 0,59 e 0,64, compatível com as amostras de IC01. Todas as amostras plotam no campo $XMg < 0,66$ e $0,33 < Al/Si < 0,8$; sendo portanto classificadas como biotitas verdadeiras com base no diagrama de Deer *et al* (1966) para classificação de biotitas.

Figura 51 - Teor de Mg vs Al/Si em biotitas de IC03 em sítios texturais distintos: matriz (triângulos), inclusão em granada (cruz), borda de granada (quadrado), inclusão em plagioclásio (losango) e borda de plagioclásio (círculo). Amostras: 03B5 (azul), 03E3 (laranja), 03F2 (vermelho) e 03J2 (verde). Formas cheias referem-se às análises no núcleo e formas vazias às bordas dos cristais.

Figura 52 - Teor de Mg vs Al/Si em biotitas da matriz de IC07: amostras 07A-C2 e 07C-C1 em azul e vermelho, respectivamente.

Figura 53 - Teor de Mg vs Al/Si em biotitas de IC01 (laranja), IC03 (verde) e IC07 (vermelho) em sítios texturais distintos: matriz (triângulos), inclusão em granada (cruz), borda de granada (quadrado), inclusão em plagioclásio (losango) e borda de plagioclásio (círculo). Formas cheias referem-se às análises no núcleo e formas vazias às bordas dos cristais.

Muscovita

Os teores de K e Na (Figuras 54 e 55) foram utilizados como base para a classificação da muscovita, separando-se em dois grupos as amostras de IC01: as amostras de 01E3, ricas em Na, e as amostras de 01C2, relativamente empobrecidas. Em IC03 o teor de Na de cristais da matriz é bastante variável e não distingue grupos composicionais específicos. Uma abordagem mais completa a respeito da composição da muscovita é apresentada no Capítulo IV – Metamorfismo e Fusão.

O aumento progressivo na quantidade de Mg das biotitas de IC01, IC03 e IC07 respectivamente, pode sugerir aumento relativo do grau metamórfico entre estas três pedreiras. A presença de Na em muscovitas de IC01 e IC03 em quantidades à partir de 2% (em relação ao K) podem indicar solução sólida com membro paragonítico, cuja quebra em presença de água ainda em fácies anfibolito poderia, juntamente com a fusão de quartzo+feldspato, contribuir para a geração de líquido sódico.

Figura 54 - Muscovitas de IC01: Teores de Na vs K para para cristais do leucossoma (quadrado), da matriz (triângulo) e inclusões em plagioclásio (losango). Amostras 01C2 (laranja) e 01E3 (verde).

Capítulo IV – Metamorfismo e Fusão Parcial

A investigação do metamorfismo e fusão parcial das rochas da unidade do Santo Antônio é feita a partir da petrografia detalhada, conjugando com os dados de química mineral e de rocha, já apresentados, a termobarometria e modelagem com pseudosseções.

Todos os cálculos de pseudosseções foram feitos com o programa THERMOCALC v3.33 (Powell e Holland, 1988), usando banco de dados termodinâmicos atualizados em 2008 (Holland e Powell, 1998). Além da modelagem com as pseudosseções, as condições P - T de pico metamórfico foram calculadas a partir de geotermobarômetros tradicionais (e.g. termômetro de granada + biotita, barômetro GASP), termômetro de Zr em rutilo (Zack *et al.*, 2004; Watson *et al.*, 2006; Ferry & Watson, 2007; Tomkins *et al.*, 2007) e através do cálculo de equilíbrio via THERMOCALC v3.33.

Modelagem metamórfica

Tendo em vista a similaridade composicional em termos de rocha total dos litotipos relacionados à unidade Santo Antônio e o reconhecimento das evidências de fusão parcial *in situ* e *in source* sem produção de feldspato potássico no resíduo ou leucossoma, a modelagem do metamorfismo tem como objetivo principal o reconhecimento das condições de pico metamórfico, fusão parcial e de cristalização do líquido neoformado, a fim de caracterizar o processo metamórfico-anatético.

A investigação parte da paragênese texturalmente estável nos xistos e metatextitos: quartzo + plagioclásio + granada + biotita + muscovita + cianita + rutilo + ilmenita + leucossoma, representante da cristalização de parte do líquido gerado; e da ausência do feldspato potássico na rocha. O cálculo das pseudosseções para litotipos aparentemente contrastantes dentro da unidade, representados por amostras das rochas mais homogêneas das pedreiras IC01 (amostra de xisto homogêneo - IC01E3) e IC03 (amostra de metatextito homogêneo - IC03F3), serve como mais uma ferramenta para avaliar a possível compatibilidade metamórfico-anatética entre os pacotes. Outras duas composições similares também foram utilizadas para avaliar a extensão dos resultados em sistemas mais cálcicos (composição SIMILAR 01), representando horizontes originalmente mais ricos em plagioclásio, ou mais magnesianos (composição SIMILAR 03), possibilitando a investigação na variação Fe-Mg dos minerais.

Os dados obtidos das amostras coletadas em campo e aqueles gerados a partir das composições similares podem ser utilizados para avaliar a extensão do metamorfismo e da fusão parcial em rochas sedimentares com déficit de potássio em relação aos pelitos, como as *wackes*, aqui chamadas informalmente de semipelitos.

Pseudosseções

A paragênese cianita + granada + biotita + plagioclásio + muscovita + rutilo + ilmenita + quartzo representa a associação mineral estável da unidade e portanto o sistema químico NCKFMASHTO foi escolhido para a modelagem das rochas. As quantidades de água e oxigênio foram fixadas respectivamente em 7% e 2% (em proporção molecular), de forma similar ao observado em rochas sedimentares na natureza (Taylor e MacLennan, 1985).

A amostra IC01E3 é caracterizada como cianita-granada-biotita-quartzo-plagioclásio xisto com muscovita, ilmenita e rutilo, de granulação fina a média e textura lepidogranoblástica, e sua composição foi utilizada como representativa das porções

mais homogêneas da pedreira IC01, cuja pseudosseção é apresentada na Figura 56. Sua topologia é composta por amplos campos de estabilidade tri- a pentavariantes, e campos menores di- a hexavariantes. Um campo univariante e um heptavariante também estão presentes. De forma geral o modelo ilustra a persistência de epídoto em condições de alta pressão, maior que 10 kbar, até pouco mais de 700 °C, mesmo em presença de líquido; a desestabilização da muscovita desde condições *P-T* relativamente brandas e antes da entrada de granada; o amplo campo de estabilidade da cianita; a entrada de feldspato potássico apenas em condições de temperatura maior que 800 °C; a quebra da biotita em condições acima de 900 °C; e a ocorrência de cordierita abaixo de 9 kbar.

As fases cianita, muscovita e feldspato potássico apresentam estreita relação, de forma que o consumo de muscovita fornece alumínio para o aumento da estabilidade da cianita, e ambas contribuem para a geração de feldspato potássico em condições mais intensas de metamorfismo. Antes do aparecimento deste mineral, o potássio remanescente da quebra da muscovita contribui para o aumento modal de biotita.

A geração de líquido ocorre ainda em fácies anfibolito, em temperatura de aproximadamente 700 °C, com o consumo da água disponível no sistema em condições acima de 10 kbar, ou pela quebra por desidratação da muscovita em pressões menores. A entrada de ilmenita se dá ainda no campo do epídoto, permanecendo estável ao longo de toda a pseudosseção. A ocorrência de rutilo é controlada pela composição da rocha,

Figura 56 - Pseudosseção obtida a partir da composição de xisto homogêneo da pedreira Santo Antônio (IC01), amostra IC01E3.

além de pressão e temperatura, e no campo de estabilidade da muscovita surge apenas em pressões acima de 10 kbar. Com a desestabilização da muscovita, biotita passa a ser a fase hidratada consumida, fornecendo titânio para o sistema, e o rutilo torna-se estável em pressões menos intensas.

A composição da amostra IC03F3, cianita-granada-biotita-quartzo-plagioclásio metatexito, com muscovita, ilmenita e rutilo, de granulação média a grossa e textura granoblástica, foi utilizada para o cálculo da pseudosseção representativa de IC03 (Figura 57). Como esperado, a topologia resultante é muito semelhante àquela de IC01, com grandes campos de estabilidade tetra- e pentavariantes, campos hepta- hexa- e trivariantes mais restritos, e diminutos campos uni- e divariantes.

Quartzo e plagioclásio são estáveis ao longo de toda a janela P - T , entretanto o campo da granada apresenta importante diferença entre estas pseudosseções: em IC01 a linha granada *in* é bem delimitada na região de pressão menor que 10 kbar, ainda em presença de água, enquanto em IC03 este mineral é estável ao longo de toda a pseudosseção. Para a amostra desta pedreira o cálculo das curvas de epidoto, ilmenita, água, líquido e rutilo foi executado com sucesso em temperaturas menores que 650 °C, mas o resultado envolve linhas com grande curvatura que podem ser resultado ou da quebra do plagioclásio para piroxênio jadeítico, o que não foi investigado, ou por problemas nos modelos de atividade dos minerais para pressões elevadas.

Em contrapartida, o cálculo do aparecimento de líquido saturado em H₂O foi problemático para IC01, exibindo como resultado uma curva H₂O *in* em temperaturas inferiores a 650 °C, que seguiria de 6 até cerca de 12 kbar, onde encontraria o invariante $liq + H_2O = 0$, do qual emanaria então a reação H₂O *out*. Tendo em vista que a modelagem do metamorfismo e da fusão parcial parte do pressuposto de que a rocha era saturada em H₂O, tais campos foram desprezados. Este problema, junto à questão do clinopiroxênio jadeítico, pode explicar a maior distorção observada nas curvas desta região de menor temperatura das pseudosseções.

Simulando possíveis horizontes mais ricos em plagioclásio e com menos sílica disponível, a composição SIMILAR 01 foi modelada (Figura 58). Embora a topologia tenha se mantido de forma geral a mesma, observa-se a desestabilização do quartzo em alta temperatura e baixa pressão, e diminuição da abrangência do campo da cordierita, que não coexiste com rutilo dentro da janela P - T calculada. Além disso, o aumento de cálcio influencia também o aumento do campo de estabilidade do epidoto, que pode chegar a temperaturas de até 750 °C em condições acima de 10 kbar.

IC03F3 - NCKFMASHTO

H2O	SiO2	Al2O3	CaO	MgO	FeO	K2O	Na2O	TiO2	O
6.846	66.748	9.232	2.112	4.714	5.105	1.526	2.846	0.675	0.196

Figura 57 - Pseudosseção obtida a partir da composição de metatextito homogêneo da pedreira INCOPE (IC03), amostra IC01F3.

Figura 58 - Pseudosseção obtida a partir de composição hipotética similar a IC01.

Isopletas composicionais de biotita, Fe#, $X_{\text{Al oct}}$, $X_{\text{Ti oct}}$ (Figura 59), muscovita, Fe#, $X_{\text{Al oct}}$, $X_{\text{Na,A}}$ (Figura 60); plagioclásio, X_{Ca} , X_{K} ; e granada, Fe#, Ca/Ca+Fe+Mg (Figura 61), foram calculadas para contornar os campos das associações minerais desta composição. Para a biotita nota-se a diminuição de ferro e aumento do alumínio octaédrico com o aumento das condições de metamorfismo, entretanto nota-se a inversão deste comportamento para o alumínio no campo muscovita *out*: as curvas sofrem forte inflexão e sua quantidade no sítio octaédrico diminui com as condições P - T . O titânio, por sua vez, é dependente da temperatura.

Na muscovita tanto o Fe# quanto $X_{\text{Al oct}}$ diminuem com o aumento da pressão, enquanto $X_{\text{Na,A}}$ diminui com o aumento de temperatura. O contorno de isopletras composicionais do plagioclásio indica o aumento da incorporação de potássio diretamente dependente da temperatura, enquanto a quantidade de cálcio diminui com o aumento da pressão. A granada, por sua vez, também tem Fe# diminuindo com o aumento das condições de P - T , enquanto a proporção de cálcio, em relação a ferro e magnésio, aumenta com a pressão e diminui com a temperatura.

Em outra simulação, uma composição rica em magnésio (cerca de 8,5% mol) designada SIMILAR 03 (Figura 62), tem como principais diferenças campos P - T menores para ilmenita, cianita e muscovita; deslocamento do campo da cordierita para temperaturas menores; aumento no campo de estabilidade do rutilo e da biotita, esta permanecendo estável em toda a pseudosseção; e condicionamento do feldspato potássico a condições superiores a 16 kbar e 900 °C. Nesta composição, a disposição das isopletras de biotita, granada e plagioclásio têm comportamento semelhante aos observados em SIMILAR 01, entretanto nota-se para a muscovita o aumento de Fe# com o aumento da temperatura, enquanto a proporção de sódio diminui neste sentido (Figuras 63 a 65). Para SIMILAR 03 foram modeladas também as isopletras composicionais de líquido (Figuras 66 e 67), as quais indicam o aumento nas quantidades de H_2O , SiO_2 , CaO e dos álcalis K_2O e Na_2O com o aumento de temperatura. Em menores intensidades de metamorfismo ocorre franco predomínio do Na_2O sobre K_2O , embora essa diferença também diminua com o aumento da temperatura. Ainda no líquido, a quantidade de ferro incorporada mostra-se dependente da composição da rocha, com aumento significativo no campo de coexistência entre ilmenita e rutilo.

Variação de Fe# [Fe/(Fe+Mg)] em biotita.

Figura 66 - Modelagem das isopletras de líquido para a composição hipotética SIMILAR 03.

Figura 67 - Modelagem das isopletas de líquido para a composição hipotética SIMILAR 03.

Embora um modelo de isoplelas não tenha sido criado especificamente para as composições originais de IC01 e IC03, puderam-se utilizar as composições similares como base para a interpretação da evolução metamórfica dessas rochas, principalmente no caso da composição SIMILAR 01, cuja topologia é bastante próxima àquela calculada para as amostras IC01E3 e IC03F3.

A composição da muscovita nas amostras IC01 pode ser dividida em dois grupos (Figura 68): o primeiro representado por cristais da matriz mais ricos em sódio (grupo 1: $\sim 0,15$ a.p.f.u.); e o segundo representado por cristais da matriz e do leucossoma, empobrecidos nesse elemento (grupo 2: entre 0,06 e 0,08 a.p.f.u.). Em relação ao Fe#, os cristais do grupo 1 apresentam núcleos enriquecidos em detrimento às bordas, enquanto no grupo 2 observa-se o enriquecimento progressivo do núcleo para bordas de cristais da matriz e leucossoma, respectivamente. A quantidade de alumínio é maior no núcleo em relação à borda nos cristais da matriz e do leucossoma do grupo 2, abrangendo o intervalo de 2,5 a 2,75 a.p.f.u.; e os cristais do grupo 1 têm teor de alumínio similar àqueles observados no leucossoma, embora note-se empobrecimento relativo das bordas neste elemento.

De acordo com as isoplelas traçadas na pseudosseção da composição SIMILAR 01, a diferença na quantidade de sódio entre a muscovita dos grupos 1 e 2 sugere diferentes estágios termais de formação, sendo que o grupo 1, mais rico em sódio, representa os cristais formados a menores temperaturas que as do grupo 2, menos rico em sódio (Figura 68, $X_{Na,A}$). A compatibilidade entre parte da muscovita da matriz e do leucossoma, grupo 2, é interpretada como evidência do aumento de temperatura, e sugere que os cristais do grupo 1 podem ser reliquias, formados antes do pico termal. No grupo 2, o aumento progressivo na quantidade de alumínio do núcleo para as bordas de cristais da matriz e leucossoma indica diminuição das condições $P-T$.

O enriquecimento em alumínio dos cristais de muscovita de matriz do grupo 1 em relação aos do grupo 2 mostra que o primeiro foi gerado em condições metamórficas mais brandas, o que reforça sua interpretação como de caráter reliquiar. O enriquecimento em ferro na borda de cristais da matriz do grupo 2 sugere reequilíbrio em regime de descompressão e a ausência dessa característica nos cristais do leucossoma pode ser explicada pelo seu isolamento, onde a ausência de outras fases ferromagnesianas restringiria o reequilíbrio do mineral. Assim, a existência de cristais reliquias oriundas de menores condições $P-T$ (grupo 1) deve estar relacionada a porções menos afetadas pela anatexia (paleossoma/resíduo), enquanto o grupo 2 deve

representar as fases cristalizadas à partir da fusão durante o resfriamento, em regime de descompressão, sugerindo trajetória metamórfica horária. Para a muscovita de IC03 o teor de sódio também se divide em dois grupos, sendo o mais rico considerado reliquiar (Figura 70). O aumento na quantidade de alumínio dos cristais da matriz em relação a inclusões em granada sugerem (re)cristalização durante descompressão.

Na biotita de IC01 (Figura 69) o aumento relativo de alumínio associado à discreta perda de titânio nas bordas dos cristais pode sugerir diminuição das condições de metamorfismo. Baseado no modelo de isopletras para biotita SIMILAR 01, no qual este comportamento é esperado para os campos sem muscovita, pode-se questionar a presença deste mineral como fase estável no pico metamórfico, no entanto a proporção modal dominante do mineral na rocha descarta essa possibilidade. Nota-se também o aumento progressivo da quantidade de titânio e diminuição do ferro nas análises realizadas em amostras de xisto homogêneo (IC01E3); xisto com bandamento composicional em escala milimétrica (IC01D2); e xisto subordinado em grande concentração de veios de quartzo (IC01C2), o que sugere que num mesmo pacote as feições estruturais podem estar condicionadas por variações locais de pressão e temperatura, de forma que estruturas desenvolvidas por esforços secundários, como pontos de descompressão geradores de fendas tensionais (*tension gashes*), bandas extencionais de cisalhamento, entre outras, podem influenciar na migração de fluidos e portanto na composição das fases minerais. Isso explica porque a amostra mais rica em veios de quartzo (enriquecida em Ti e empobrecida em Fe) parece ser formada em maior temperatura e menor pressão que as demais. Para IC03 a composição da biotita apresenta dispersão aleatória (Figura 71), o que pode ser indício de homogeneização em condições mais intensas de metamorfismo.

O plagioclásio de IC01 apresenta diminuição no teor de anortita e aumento na molécula de oligoclásio dos cristais inclusos para aqueles relacionados à matriz e leucossoma, respectivamente, indicando o aumento relativo de temperatura na formação das diferentes fases. O plagioclásio de IC03, assim como a biotita analisada nas amostras dessa pedreira, apresenta dispersão aleatória, embora note-se enriquecimento relativo dos cristais de leucossoma na molécula ortoclásio e discreto ganho de anortita das bordas em relação ao núcleo dos minerais.

Termobarometria

Os cálculos termobarométricos foram realizados por diferentes métodos: termobarometria convencionalmente aplicada a pelitos (termômetro granada + biotita de Bhattacharya *et al.*, 1992; barômetros tipo GASP, GPMB-Mg, GPMB-Fe - Spear, 1993; Holland e Powell, 1993; Waters, 2004); média *P-T* via THERMOCALC v3.33 para associações selecionadas por afinidade química; e termômetro de Zr em rutilo nas amostras cuja composição foi modelada, além de cristais pertencentes a amostras da pedreira IC07, imediatamente sotoposta à IC03.

Tendo em vista que associações minerais consideradas como em equilíbrio textural não necessariamente representam um equilíbrio químico, e que um dos objetivos deste trabalho é reconhecer as condições do pico metamórfico, o cálculo das condições *P-T* foi feito com base na composição química de minerais do mesmo sítio textural na seção delgada. Esta metodologia visa escolher as melhores combinações que, de acordo com os modelos de isopletras observados na composição SIMILAR 01, representem a associação de maior temperatura para as rochas em questão. Assim, foram selecionadas análises de micas e bordas de granada mais magnesianas, e bordas mais cálcicas em plagioclásio, todos os minerais pertencentes à matriz e dentro do mesmo campo de observação na seção delgada. As condições de pico estimadas para IC01 foram calculadas em 745 ± 22 °C e $11,56 \pm 1,04$ kbar; e para IC03 850 ± 24 °C e $8,71 \pm 0,91$ °C. Deve-se ressaltar que nestes cálculos, os parâmetros *P-T* foram calculados individualmente, a fim de reduzir as incertezas obtidas e comparar com os cálculos concomitante para ambas as variáveis (método average *PT*, Powell & Holland, 1994). Os cálculos feitos desta maneira produzem condições *P-T* muito próximas dos cálculos feitos de forma separada, mas com valores de incertezas muito maiores.

Utilizando a calibração de Tomkins *et al.* (2007), o termômetro Zr *in* rutilo (Zack *et al.*, 2004; Watson *et al.*, 2006; Ferry & Watson, 2007) foi utilizado para calcular as temperaturas máximas de cada unidade: para IC01 a quantidade de Zr em rutilo variou entre 511 e 620 ppm, correspondendo a temperaturas entre 713 °C a 10 kbar e 762 °C a 15 kbar (Figura 73). Para IC03 a quantia de Zr em rutilo é de 515 a 749 ppm, e a temperatura máxima variou entre 729 °C a 10 kbar e 753 °C a 15 kbar (Figura 74). Foram obtidos também dados em rutilo da pedreira IC07, imediatamente sotoposta a IC03, já reconhecida em trabalhos anteriores como pertencente à unidade Santo Antônio (e.g. Trouw *et al.*, 2007). Nesta amostra foram analisados cristais em

equilíbrio, sem alteração visível, com teor de Zr entre 554 e 777 ppm originando temperaturas de 733 °C a 10 kbar até 756 °C a 15 kbar (Figura 75).

As Figuras 76 e 77 reúnem todos os resultados de pico metamórfico calculados para as pedreiras IC01 e IC03, respectivamente. As diferenças observadas entre os valores obtidos via média *P-T* com o THERMOCALC e aqueles obtidos via termobarômetros tradicionais pode ser explicada de diversas maneiras, incluindo: a incerteza das composições de equilíbrio das micas consideradas, talvez tardias em relação ao pico metamórfico; a ausência de análises de ilmenita, o que impossibilita a consideração das variações na solução sólida do mineral e sua relação com a geração de rutilo, tornando imprópria a introdução destas fases nos cálculos de pico metamórfico; e a consideração de composições progressivamente mais cálcicas na evolução do plagioclásio adotado pelo geobarômetro GASP, desconsiderando a adição da molécula sódica devido ao processo anatético; ou ainda à imprecisão inerente a todas as calibrações utilizadas. Além disso, a diferença entre estes resultados e aqueles obtidos através do termômetro de Zr em rutilo pode ser resultado de enviesamento por sub-amostragem, já que poucos cristais foram analisados em apenas uma seção delgada de cada pedreira estudada. A discrepância é ainda maior nos resultados de IC03, pelo fato de que a amostra em que rutilo foi analisado é diferente da amostra utilizada para os outros métodos de termobarometria, embora da mesma pedreira.

De acordo com os resultados calculados pode-se afirmar que as rochas da unidade Santo Antônio tiveram seu pico metamórfico entre 750 e 850 °C, da base para o topo da unidade. Embora os dados de pressão resultem em condições máximas de aproximadamente 11,5 kbar, a presença de rutilo e ilmenita sugerem pressões mais altas para o regime metamórfico. O campo trivariante líquido + biotita + granada + muscovita + plagioclásio + ilmenita + rutilo + cianita + quartzo, bem representado em ambas as pseudosseções calculadas para IC01 e IC03, é compatível com esta interpretação, e por representar a paragênese de equilíbrio reconhecida nas amostras, pode ser considerado portanto o melhor representante das possíveis condições de pico metamórfico para esta unidade. O cálculo *P-T* para o pico metamórfico para a amostra IC03 resulta em condições de temperaturas bastante elevada e pressão relativamente baixa, quando comparados com os resultados de IC01, além disso as condições *P-T* resultantes ficam dispostas dentro de campo na pseudosseção que não contempla a associação mineral observada na rocha. Investigações mais detalhadas serão feitas com essas amostras.

Estudos complementares de termobarometria baseada em equilíbrio químico e textural, novas análises em cristais de rutilo, e modelagem de isopletras composicionais e de moda mineral específicas para as composições de IC01 e IC03 devem ser alvo de publicações em futuro próximo. A obtenção de idades relativas entre porções distintas do metatexito, assim como análise estrutural e incorporação da influência de manganês nos modelos calculados devem ser temas para trabalhos futuros.

Capítulo V – Discussão

As pedreiras IC01, IC03 e IC07 representam a variação de litotipos observada na unidade Santo Antônio, sendo que as rochas expostas são cianita-granada-biotita-quartzo-plagioclásio xistos e metatexitos, cujas estruturas e texturas variam de acordo com a taxa de fusão atingida. Os domínios basais são compostos majoritariamente por xistos de granulação fina a média, com feições locais de fusão parcial restrita (IC01), e os domínios superiores compostos por metatexitos de granulação média a grossa, nos quais a ampla distribuição de leucossoma tipo *patches* e veios tonalíticos, em geral envoltos por filmes de biotita, atribuem aspecto paragnáissico à rocha através do desenvolvimento local de estrutura estromática (IC03 e IC07). Embora esta compartimentação maior seja clara, entre xisto e metatexito, ambos os pacotes apresentam heterogeneidades composicionais que controlam a ocorrência de fusão parcial.

Embora anteriormente as rochas aqui estudadas tenham sido separadas em unidades diferentes, unidade Santo Antônio (IC01 e IC07) e Arantina (IC03; Trouw *et al.*, 2007), a química de rocha total evidencia a similaridade composicional dos litotipos, o que ajuda a reuni-los em única unidade. Algumas diferenças, no entanto, são observadas, tais como o enriquecimento de Si e Na nas unidades de topo (IC03, IC07) em detrimento de K, Fe e Mg, mais abundantes porções basais (IC01). A diferença de granulação e estrutura e variação na proporção modal dos minerais nas amostras estudadas, podem ser explicadas pelo reconhecimento da fusão *in situ* ou *in source*, indicando alguma segregação do fundido, que pode ocorrer em porções isoladas nos domínios xistosos, principalmente onde há veios de quartzo em abundância (e.g. IC01); ou de forma penetrativa, definindo domínios de metatexitos (e.g. IC03), anteriormente correlacionados à unidade Arantina. A comparação química entre amostras de xisto, metatexito e leucossoma mostram que o líquido foi gerado a partir da fusão de quartzo e plagioclásio como fases principais, dado o enriquecimento em Na, Ca, Si e Sr, além de anomalia positiva de Eu nas amostras de leucossoma. A similaridade dos padrões de elementos terras raras em amostras de xisto e metatexito comprovam que não houve diferenciação composicional significativa entre estes litotipos, indicando baixas taxas de fusão e segregação, e ainda sugerindo que a fusão parcial não ocorreu em temperaturas muito altas, permitindo a retenção de elementos como U, Th e Zr nos xistos e

metatextos, o que implica na não fusão de fases como apatita, monazita e zircão. A composição do leucossoma também converge para a mesma interpretação, já que é pobre em todos os elementos menores e traço, sendo apenas enriquecido em Eu.

Em relação à química mineral, os dados de plagioclásio destacam-se como evidência do processo anatético, formando tendência contínua progressivamente mais rica na molécula de albita, para cristais inclusos em granada, da matriz e do leucossoma, sendo que esta diferença torna-se menos clara de IC01 para IC03 e IC07. O enriquecimento progressivo em albita também é observado das amostras de IC01 para IC03 e IC07, indicando a geração de líquido rico em sódio, evidenciado pelo aumento do componente da albita no leucossoma, como é visto na modelagem com as pseudosseções, e o aumento da taxa de fusão para o topo do pacote, como sugere não só o aumento no teor de albita, mas também a maior homogeneidade observada na composição dos cristais de plagioclásio de IC03 e IC07.

A similaridade composicional entre xistos e metatextos também é refletida na topologia das pseudosseções do sistema NCKFMASHTO calculadas para amostras homogêneas de IC01 e IC03, respectivamente, o que ratifica a compatibilidade dos litotipos. A geração de líquido em temperaturas algo acima de 700 °C, ocorre pelo consumo da água, em excesso no sistema, somada à fusão por desidratação da muscovita, em regime de pressão de 10 kbar, mas antes da reação granada *in*. O consumo do mineral fornece alumínio e potássio para o sistema, favorecendo a geração de cianita e biotita, com entrada do feldspato potássico apenas em condições de temperatura superior a 800 °C. Os modelos de isopletras composicionais mostram a geração de fundido rico em sódio, sílica e água, compatível com o leucossoma reconhecido em campo, e com os dados de geoquímica de rocha total e mineral. Além do plagioclásio, a muscovita mostrou-se um bom indicador das condições de metamorfismo: a variação de Na em cristais de distintos sítios texturais mostra a presença de um grupo reliquiar ou residual, gerado em condições de menor temperatura na matriz; e um grupo formado em temperatura mais alta, no qual a variação núcleo-borda nos teores de ferro e alumínio mostram a cristalização em regime de descompressão, caracterizando trajetória metamórfica horária.

O termômetro Zr em rutilo apresentou dados consistentes com os cálculos das condições de pico metamórfico via THERMOCALC para a pedreira IC01, representante dos litotipos xistosos da unidade. Embora haja discrepância dos resultados calculados em IC03, representante dos metatextos, a correlação com as evidências de fusão

observadas em escala meso e microscópica, respaldadas pela química mineral e cálculo de pseudosseções, juntamente com os dados de rutilo obtidos para IC07, sugere o aumento da temperatura, e consequentemente da anatexia, para as camadas de topo do pacote, caracterizando assim o metamorfismo invertido da área. As condições de pico metamórfico devem variar, da base para o topo, entre 750 e 850 °C, respectivamente, dentro do campo trivariante definido pela paragénese líquido + biotita + granada + muscovita + plagioclásio + ilmenita + rutilo + cianita + quartzo. As temperaturas calculadas de 850 °C podem ser algo elevadas para a taxa de fusão observada e novas investigações serão feitas para confirmar o resultado.

A partir dos resultados do termômetro de Ti em quartzo e modelagem metamórfica com pseudosseções, Reno *et al.* (2011) argumentam que a trajetória *P-T* é de descompressão, e que a rocha na pedreira de IC03 alcançou as condições para geração de feldspato potássico, com retrometamorfismo posterior responsável pela transformação destes minerais em biotita. Os autores também afirmam que as monazitas utilizadas para datação cujo resultado reflete o evento mais jovem ligado à *nappe* Carmo da Cachoeira, 600-595 Ma, são de dissolução e reprecipitação gerada pela liberação de fluidos com o alcance da curva *solidus*, durante o estágio de exumação da *nappe*.

Os dados aqui apresentados, entretanto, sugerem trajetória *P-T* horária, no qual o consumo de água e muscovita, em presença de plagioclásio, dão origem a líquido rico em sódio, representado agora por leucossoma composto de quartzo e plagioclásio. Além da biotita pré-existente, esta evolução favorece a geração biotita e cianita peritéticas residuais. O potássio incorporado no líquido é representado, em contrapartida, pela cristalização de muscovita tardia associada a estes sítios, além de biotita no melanossoma ou ainda retrometamórfica, que ocorre nos contatos entre bolsões de fundido e a matriz, de forma a “encapsular” localmente algumas segregações de leucossoma. A química de rocha total mostra ainda a retenção de elementos terras-raras nos litotipos de afinidade residual/paleossoma em relação ao leucossoma, indicando portanto limitação para processos de dissolução e reprecipitação de fases acessórias como monazita e zircão. Deste modo, o presente trabalho não sustenta de forma alguma as conclusões e proposições feitas para a *nappe* Carmo da Cachoeira por Reno *et al.* (2009, 2011).

Capítulo VI – Conclusões

O reconhecimento geológico em campo, aliado aos dados de geoquímica de rocha total e mineral obtidos para amostras das pedreiras IC01, IC03 e IC07, evidenciam a origem dos litotipos por elas representados a partir da evolução de processo anatético incipiente a moderado, favorecido pela presença pervasiva de veios de quartzo, onde a fusão se inicia pela disponibilidade preferencial de fluidos e através da reação de desidratação da muscovita, gerando líquido rico em Si e Na, cristalizado como leucossoma composto por quartzo e plagioclásio, além de cianita e biotita como fases residuais.

A limitação nas proporções dos veios de leucossoma observados nos diversos afloramentos, restritos a *patches*, veios e bolsões descontínuos e pouco espessos, retidos *in situ* ou na fonte, associada a não existência de litotipos verdadeiramente residuais e à conspícua compatibilidade das composições de rocha total dos diversos litotipos amostrados nas pedreiras, evidencia a limitação para segregação do líquido gerado. Esta evidência é compatível com a similaridade composicional observada também nos padrões de elementos terras-raras dos diversos litotipos amostrados, que sugerem a não dissolução de fases acessórias como monazita e zircão.

As características apresentadas permitem interpretar as rochas das pedreiras IC01, IC03 e IC07 como pertencentes à mesma unidade, no caso a unidade Santo Antônio de Trouw *et al.* (2007), que pode ser redefinida para a área de estudo como metatexito com taxas de fusão variáveis, incipiente na base aumentando para topo. A modelagem metamórfica mostra o campo de estabilidade trivariante definido pela associação líquido + biotita + granada + muscovita + plagioclásio + ilmenita + rutilo + cianita + quartzo como representante das condições de pico metamórfico. Nestes termos, o cálculo da termobarometria permitiu estimar temperaturas de 750 a 850 °C da base para o topo da unidade Santo Antônio, caracterizando o metamorfismo invertido na região.

Assim, pode-se dizer que o presente trabalho contribui para o conhecimento do processo anatético em rochas de composição semipelítica, destacando-se a geração de líquido silicático rico em sódio e grande extensão do consumo de muscovita sem geração de feldspato potássico. A similaridade composicional entre os litotipos observados nas diversas pedreiras, a retenção de fases refratárias na rocha e a escassez de grandes volumes de leucossoma segregado indicam não só a anatexia em condições

metamórficas moderadas, mas também a limitação na quantidade de fundido gerado e segregado. A ausência de segregação do líquido de forma eficaz auxilia no retrometamorfismo da rocha, com consumo de parte do líquido aprisionado, resultando em produto final, que quimicamente acaba não sendo muito diferente da composição geral pré-fusão.

Zona Cisalhamento Três Corações

Falha inversa

Unidades

Depósitos Aluvionares - Cascalho, areia e lama inconsolidada.

Unidade Arantina - Intercalações submétricas de muscovita quartzito xistos, quartzitos e biotita xistos com granada e plagioclásio.

Unidade Santo Antônio - Biotita xisto/metatexito rico em plagioclásio, com granada, cianita, rutilo, muscovita e ilmenita.

Unidade São Vicente - Biotita paragneisse bandado com intercalações de quartzito, muscovita-quartzito xisto e anfibolito, localmente migmatítico.

Unidade São Vicente - Granada-anfibolito-clorita xisto e anfibolito

Unidade São Vicente - Muscovita quartzito xistos e quartzitos

Unidade São Tomé das Letras - Quartzitos com intercalações de quartzito xistos.

Complexo Mantiqueira - Ortognaisses migmatíticos com intercalações de anfibolitos e metaultramáficas
