À Maria Ignez e nossos filhos, Rafael, David e Maria Olivia. Minhas maiores inspirações e propósitos para seguir sempre em frente.

AGRADECIMENTOS

Ao Prof. Dr. Daniel Ciampi de Andrade, pela amizade ao longo dos anos, ensino e parceria durante esse projeto.

Ao Prof. Manoel Jacobsen Teixeira, pela formação, ensino e estímulo a sempre buscar mais do que lugar comum.

Ao Prof. Dr. Robson Amorin, pela amizade e criação desse projeto.

Ao Prof. Dr. Erich Fonoff, pela parceria e ensino na área de dor.

À Profa. Dra. Silvia Siqueira, pelo auxílio em aprender sobre um tema tão rico e complexo.

Ao Dr. Ricardo Galhardoni, pela parceria e ajuda no desenvolvimento do projeto.

À Dra. Cristiane Fukuda, pela parceria em desenvolver e executar esse trabalho longo e complexo.

Ao Dr. Mario Gilberto Siqueira, pela amizade paternal, paciência, oportunidade de me tornar um neurocirugião melhor.

Ao Dr. Roberto Sérgio Martins, pela amizade e oportunidade de aprender mais todo dia.

Ao Dr. Iuri Neville, pela amizade e parceria nos momentos de dúvida.

A minha esposa, Maria Ignez, pelo companherismo e paciência.

Aos meus pais, por me fornecerem a oportunidade de ser quem sou hoje.

Aos médicos residentes, pela ajuda na realização do projeto.

E principalmente aos pacientes, motivo e razão da existência do nosso trabalho, empenho e dedicação ao realizar esse ofício.

Without music to decorate it, time is just a bunch of boring production deadlines or dates by which bills must be paid.

RESUMO

Sterman Neto H. *Avaliação comparativa dos efeitos da termocoagulação por radiofrequência e neurotomia percutânea com balão no controle da dor a longo prazo em pacientes com neuralgia trigeminal idiopática* [tese]. São Paulo: Faculdade de Medicina, Universidade de São Paulo; 2022.

Introdução: a neuralgia trigeminal, a despeito de reconhecida há séculos, continua sendo a síndrome dolorosa neuropática facial mais fascinante e desafiadora no que se refere ao seu tratamento. Apesar de sua primeira descrição formal ter ocorrido no século 18, os tratamentos mais eficazes surgiram somente após meados do século 20. Contudo, há uma escassez de dados em estudos comparativos com alto nível de evidência entre os métodos. Dessa forma, o presente estudo comparou a eficácia dos procedimentos percutâneos mais frequentemente utilizados no controle álgico dos pacientes com neuralgia trigeminal. Métodos: trata-se de um ensaio clínico prospectivo aleatorizado, duplamente encoberto, que incluiu 33 pacientes com diagnóstico de neuralgia trigeminal, em dois grupos: BC (neurotomia por balão) e RF (termocoagulação por radiofrequência). Os pacientes foram avaliados em seis momentos distintos: antes do procedimento (V0), sete (V1), 30 (V2), 60 (V3), 90 (V4) e 180 (V5) dias após. Foram utilizadas escalas para avaliação de dor (BPI, NPSI, DN4, SF-MPQ), quantidade de medicação utilizada (MQS), qualidade de vida (WHOQoL – BREV) e funções psicológicas e humor (PCS e HADS). Dados sociodemográficos foram analisados entre os grupos. Foi utilizado, como desfecho primário, o terceiro item do BPI (escala numérica de dor nas últimas 24 horas). Após randomização, os pacientes foram submetidos ao procedimento sorteado. O desfecho primário foi analisado utilizando modelo de regressão linear. Teste t de Student foi usado para variáveis de distribuição normal e o teste de Mann-Whitney e qui-quadrado para variáveis de distribuição não-normal. Fora realizada análise interina pré-planejada com pelo menos metade dos pacientes planejados. Resultados: para a análise interina, dados de 33 pacientes estavam disponíveis. A idade média foi de 62,18 ± 9,4 anos. O objetivo primário não apresentou diferença estatisticamente significativa entre os grupos ao final do estudo. A taxa de complicação foi semelhante. A influência da dor nas atividades de vida diárias, as dimensões da dor, sintomas de dor neuropática, humor, quantidade de medicação em uso e qualidade de vida, avaliados com questionários específicos, também não apresentaram diferença estatisticamente significativa. O grupo de RF apresentou mais sintomas parestéticos do que o grupo BC (2,08±1,99; 3,97±1,96; p = 0,017) nos 30 dias subsequentes à intervenção, a despeito de não ter crises de dor (4,55±0,78, 5±0; p = 0,015). A presença do componente de dor contínua foi semelhante nos grupos. O estudo foi interrompido por insignificância clínica. Conclusão: os dois métodos possuem capacidade de controle de dor semelhante. Registro do ensaio no ClinicalTrials.gov – NCT02427074.

ABSTRACT

Sterman Neto H. *Comparative evaluation between radiofrequency thermocoagulation and balloon compression neurotomy on long-term pain control in patients with idiopathic trigeminal neuralgia* [thesis]. São Paulo: "Faculdade de Medicina, Universidade de São Paulo"; 2022.

Introduction: trigeminal neuralgia, despite being recognized for centuries, remains the most fascinating and challenging facial neuropathic painful syndromes in terms of its treatment. The most effective treatments appeared after the middle of the 20th century. However, well-designed studies comparing the main therapeutic methods are lacking. The aim of this study was to compared the effectiveness of the most frequently used percutaneous procedures for pain control in patients with trigeminal neuralgia. Methods: a prospective randomized, double-blind, intention-to-treat, clinical trial, was performed: 33 patients diagnosed with trigeminal neuralgia were available for the pre-planned interim analysis. Patients were randomized using an online program. After randomization, patients were divided in two groups: balloon compression (BC) and radiofrequency (RF). Patients were evaluated at six different times: before the procedure (V0), and 7 (V1), 30 (V2), 60 (V3), 90 (V4) and 180 (V5) days after the procedure. Scales were used to assess pain (BPI, NPSI, DN4, SF-MPQ), quantity of medication used (MQS), quality of life (WHOQoL - BREV) and psychological functions and mood (PCS and HADS). Sociodemographic data were compared between the groups. The primary outcome was the third item of the BPI (numerical scale of the worst pain in the last 24 hours). The main outcome was assessed using generalized estimation equations. Student t-test was used for the normally distributed variables and Mann-Whitney and Pearson's chi-square test for the non-normally variables. A pre-planned interim analysis was performed when at least half of the estimated sample size was allocated. Results: thirty-three patients were available for the interim analysis (18 in BC and 15 in RF group). The average age was 62.18 ± 9.4 years. The primary objective showed no difference statistically significant between groups at the end of the study. Both groups presented similar complication rates. The influence of pain on daily activities of life, dimensions of pain, symptoms of neuropathic pain, mood, quantity of medication in use and quality of life, assessed with specific questionnaires, also showed no statistically significant difference. The RF group had more paresthetic symptoms than the BC group (2.08±1.99, 3.97±1.96; p=0.017) in the 30 days after the intervention, despite having no pain attacks (4.55±0.78, 5±0; p=0.015). The presence of continuous pain was similar in both groups. The study was interrupted due to futility. Conclusion: both methods show similar capacity in pain control. ClinicalTrials.gov Registry – NCT02427074.

1 INTRODUCTION

Trigeminal neuralgia (TN) is characterized by shock-like paroxystic attacks distributed in one or more trigeminal branches. These attacks may occur spontaneously, or may be evoked by mechanical triggers such as lightly touching the skin, brushing teeth, chewing or even talking (Casey, 2005). It has been hypothesized that TN is triggered by contact between vessels and the root entry zone of the fifth cranial nerve (Nurmikko and Eldridge, 2001). However, recent data suggest that not only nerve deformation caused by a vessel, but also other factors relating to the trigeminal ganglion, the trigeminal nucleus or abnormalities in sodium channels may play a role in the initiation of symptoms (Siqueira *et al*., 2009; Montano *et al*., 2015). It has been estimated that TN affects from 4 to 13 per 100,000 individuals-year, and that it tends to affect predominantly women (1:1.5 to 1:1.7). The right side of the face is affected more commonly than the left side (Katusic *et al*., 1990; MacDonald *et al*., 2000; Casey, 2005; Gronseth *et al*., 2008; Obermann and Katsarava, 2009; van Kleef *et al*., 2009; Maarbjerg *et al*., 2017).

TN is initially managed with medication. Based on systematic reviews and randomized controlled trials, carbamazepine (CBZ) has been strongly recommended as the initial drug of choice (Campbell *et al*., 1966; Rockliff and Davis, 1966; Killian and Fromm, 1968; Rasmussen and Riishede, 1970; Wiffen *et al*., 2014). Oxcarbazepine (OXC) is a good option with better tolerability than CBZ and reasonable pain control, although no comparison with placebo has been made (Liebel *et al*., 2001; Beydoun, 2002; Besi *et al*., 2015).

Despite the fact that up to 90% of individuals will initially achieve pain control through pharmacological treatment, some will eventually need surgical intervention in order to alleviate pain, either because of intolerable side effects or refractory pain. There are no large studies addressing long-term pharmacological failure, but some small studies have suggested that approximately half of TN patients will eventually fail to respond to medical treatment over a ten-year period (Taylor *et al*., 1981; McQuay *et al*., 1995; Fields, 1996; Casey, 2005; Cruccu *et al*., 2008; Holland *et al*., 2015). The surgical interventions that have been applied include posterior fossa procedures (commonly microvascular decompression, MVD) (Jannetta, 1967) and trigeminal ganglion (GG) interventions such as radiofrequency thermocoagulation (RF) and balloon compression (BC) (Sweet and Wepsic, 1974; Mullan and Lichtor, 1983). The RF and BC approaches are destructive procedures that led to various degrees of sensory changes. MVD can achieve long-term pain relief in up to 70% of patients (Brisman, 2007; Linskey *et al*., 2008; Pollock and Schoeberl, 2010; Wang *et al*., 2018) with no sensory disturbance in the postoperative period, albeit its highest risk of postoperative complications (stroke, meningitis, cerebral spinal fluid leak, hemorrhage in 2% and death in 0.4% of the patients) (Huibin *et al*., 2009; Zakrzewska and Linskey, 2009). Despite the increasing number of series reporting good outcomes after MVD, percutaneous procedures are still commonly used worldwide (Noorani *et al*., 2016; Yao *et al*., 2016).

Since trigeminal ganglion procedures are less invasive and available, they became the intervention of choice in most pain centers (Sweet, 1975; Apfelbaum, 1977; Lichtor and Mullan, 1990; Tronnier *et al*., 2001; Teixeira *et al*., 2006; Baabor and Perez-Limonte, 2011; Koopman *et al*., 2011; Kundu and Rolston, 2018). Up to

80% of the subjects treated with BC and RF may be free of pain depending on the follow-up period (Kanpolat *et al*., 2001; Bendtsen *et al*., 2019; Jones *et al.*, 2019), although the end-points are not clear in the literature. The degree of pain control achieved through ablative approaches varies among the published reports (Sengupta and Stunden, 1977; Skirving and Dan, 2001; Teixeira *et al*., 2006; Tatli *et al*., 2008; Texakalidis *et al.*, 2019). Facial hypoesthesia can occur in 19% of individuals in RF and 14% in BC; masticatory weakness 6% in RF and 4.5% in BC; corneal numbness in 6.6% in RF and 0.7% in BC and painful anesthesia in 0.1 to 4% in both, although the latter more frequent in RF (Bendtsen *et al*., 2019; Jones *et al.*, 2019).

Trigeminal neuralgia classification is another issue that evolved through time and still is a matter of debate. Predate to formal classification, facial pain was divided into three major types: typical TN (*tic* douloureux), atypical TN and atypical facial pain, depending on the predominant symptom (paroxysms in typical, constant in atypical TN and no paroxysms in atypical facial pain) (Burchiel and McCartney, 2015).

Another form of classification published in early 2000's (Burchiel, 2003; Eller *et al*., 2005), classified the pain originated in the trigeminal nerve in specific groups, based on patient history and symptom onset (spontaneous or post-injury): TN1, TN2, trigeminal neuropathic pain, trigeminal deafferentation pain, symptomatic TN, postherpetic TN and atypical facial pain.

The 2004 IASP/HIS Classification separated TN individuals in two groups: classic TN (essential and idiopathic) and symptomatic TN (similar pain to classic TN but with demonstrated structural anomaly other than vascular compression) (Obermann and Katsarava, 2009).

Over time, classification has evolved until Cruccu *et al*. (2016) and IASP/IHS later, stablished the current definition and subtypes (Chart 1). It accounts for two major groups: TN and painful trigeminal neuropathy. The latter is subsequently divided in classical, secondary and idiopathic. In order to classify TN, individuals must perform a MRI, since vascular compression must be investigated. The classification also incorporated some terms referring to prevailing symptoms: "purely paroxysmal" and "with concomitant continuous pain", which does not carry any relation to etiology. Chart 2 summarizes the evolution of terms overtime.

Chart 1 - Diagnostic criteria of TN according to IASP/HIS (Headache Classification Committee, 2018)

A)	Recurrent paroxysms of unilateral facial pain in the distribution(s) of one or more divisions of the trigeminal nerve, with no radiation beyond, and fulfilling criteria B and C
B)	Pain has all of the following characteristics: 1. Lasting from a fraction of a second to two minutes 2. Severe intensity 3. Electric shock-like, shooting, stabbing or sharp in quality
C)	Precipitated by innocuous stimuli within the affected trigeminal distribution
D)	Not better accounted for by another ICHD-3 diagnosis

Chart 2 - Evolution of TN classification over time

	Until 2000's	2003-2005	IASP/IHS 2004	Since 2016	
TN	Tic doulourex	TN1	Classic TN	TN (Classical and idiopathic)	Every type can present: - Purely paroxysmal - With concomitant continuous pain
TN	Atypical TN	TN2	Classic TN	TN (Classical and idiopathic)	Every type can present: - Purely paroxysmal - With concomitant continuous pain
Others	Atypical facial pain	trigeminal neuropathic pain	Symptomatic TN	Secondary TN	Every type can present: - Purely paroxysmal - With concomitant continuous pain
Others	Atypical facial pain	trigeminal deafferentation pain	Symptomatic TN	Painful trigeminal neuropathy	Every type can present: - Purely paroxysmal - With concomitant continuous pain
Others	Atypical facial pain	symptomatic TN	Symptomatic TN	Painful trigeminal neuropathy	Every type can present: - Purely paroxysmal - With concomitant continuous pain
Others	Atypical facial pain	postherpetic TN	Symptomatic TN	Painful trigeminal neuropathy	Every type can present: - Purely paroxysmal - With concomitant continuous pain
Others	Atypical facial pain	atypical facial pain	Symptomatic TN	Painful trigeminal neuropathy	Every type can present: - Purely paroxysmal - With concomitant continuous pain

Table presenting the changes throughout the years in TN classification and grouping

Despite not being addressed in the classification, classical and idiopathic TN may be referred to as primary (as in non-secondary) TN, since the use of the aforementioned terms impact more the therapeutic than diagnostic aspects (Bendtsen 2019).

The evolution of TN classification proved useful overtime since differences in pain presentation were not looked upon previously. Despite this improvement, the inclusion of MRI to the current criteria possesses a barrier to countries that present with limited resources. Even more, the presence of vascular compression may be only useful to individuals that may be prone to receive MVD. Nonetheless, percutaneous procedures are still largely used and, to these subjects, the presence of the deformation of the fifth nerve is not essential to select treatment. For this reason, the use of contrast-enhanced CT-scans, in order to discard space occupying lesions, still has its role and should not be overlooked.

Despite the results from percutaneous procedures having been extensively reported, no formal comparison between BC and RF has been studied. The available data comes from large case series and retrospective cohorts and, therefore, very low level of evidence exists (Attachment A). Until the present moment, it remains largely unknown which of the two techniques is the more effective and, moreover, what their real profiles of pain relief and prevalence of adverse events related to them are. In addition, TN may present with non-paroxysmal pain associated with its classical paroxysms (Zakrzewska and Akram, 2011). The effects of treatment on these different types of pain has never been formally addressed to date.

Here, we conducted an original prospective head-to-head randomized trial to assess superiority of RF over BC in controlling trigeminal pain.

2 OBJECTIVES

2.1 Primary Objective

The main objective of the present study was to evaluate the superiority of RF over BC in trigeminal pain control at six months from surgery.

2.2 Secondary Objectives

- To assess pain characteristics (presence of continuous pain and temporal features).
- To assess mood and quality of life.
- To assess and evaluate onset of new forms of pain and recurrence as well as their characteristics.

The questionnaires applied to evaluate the secondary objectives will be used in further thesis with the intention to analyze a prediction model of outcome.

3 REVIEW OF LITERATURE

3.1 Overview of the Historical Aspects

Trigeminal neuralgia is a unique neuropathic pain syndrome. Supposedly known for hundreds of years since first reports from Greek physicians, Arataeus of Cappadocia and Galen, in the 2nd century AD (Rose, 1999; Eboli *et al*., 2009), later studies suggested that these reports related more closely to atypical TN or migraine than to typical TN (Stookey and Ransohoff, 1959). Avicenna in the 11th century AD also described craniofacial disorders (Ameli, 1965), but he only portrayed two patients, one of which most likely had facial palsy (Lewy, 1938).

Although the first full description is credited to John Locke in 1677 (Lewy, 1938; Pearce, 1993; Rose, 1999) (whom, upon examining the wife of the English ambassador suffering from intense pain on the face and jaw, prescribed laxatives as treatment), the first documented report of TN was published in 1688, narrating the progressive deterioration of Johannes Laurentis Bausch of Germany until his death in 1665, due to starvation caused by excruciating facial pain that forbid him to dwell (Cole *et al*., 2005; Eboli *et al*., 2009).

Nicholas Andre in 1756, describing two individuals with TN, that presented with facial contraction (resembling that of epileptic seizures) during pain attacks, coined the term *tic douloureux* (Brown *et al*., 1999; Cole *et al*., 2005). He was also a pioneer in treating patients, following the works of Marechal (Stookey and Ransohoff, 1959; Pearce, 1993), who believing that “vicious nervous liquids”

distressed the nerve causing pain, frequently instilled caustic substances in the infra-orbital nerve until its destruction.

A complete and detailed documented description occurred in 1773 by Fothergill therefore later being also known as Fothergill's Disease (Eboli *et al*., 2009). Although not frequently cited, John Hunter had also contributed during that century because of his interest in nerve anatomy (Eboli *et al*., 2009). He is most likely to be the first to describe nerve pain.

Its pathophysiology, deemed complex in nature since many factors may play a role, could be better understood after the discovery of the trigeminal nerve, its difference from the facial nerve, and its relation to the disease, by Charles Bell in 1829 (almost simultaneously as Mangedie). Therefore, the trigeminal nerve was held responsible for the illness (Cole *et al*., 2005), and named trigeminal neuralgia.

In the 1930s, the observations of Dandy stablished that demyelinization at the root entry zone was probably caused by pulsation of micro vessels to the nerve (Dandy, 1934), confirmed later by the observations of Jannetta, in 1967. A common denominator was frequently present: demyelization of the root entry zone of the fifth cranial nerve, either by a compressing vessel, tumor, multiple sclerosis or infection. This event is thought to generate ectopic action potential through ephatic transmission by Aβ-fibers and, associated with neuronal reorganization, led to misrouting of non-painful stimuli (talking, chewing, wind, light touch) to painful paths (allodynia), which prompts the painful shock-like attacks and may explain the trigger zones of the face (Casey, 2005; Eller *et al*., 2005; Obermann and Katsarava, 2009). Albeit the discovery that neurovascular compression can play a more important role in initiation (Antonini *et al*., 2014), it may be seen in asymptomatic

individuals and, therefore, a predisposed condition may also account for this variability (Siqueira *et al*., 2009).

Another hypothesis has been proposed. Devor *et al*, in 2002, published an excellent work explaining the "Ignition Theory" in which morpho- and physiological changes created by demyelination could explain the disease as a whole.

3.2 Treatment Evolution

3.2.1 Medical treatment

Early medical treatment dates from the works of Fothergill, where he suggested the use of Peruvian bark, which contained quinine (an alkaloid agent) o treat TN. For the following 150 years, a number of medical treatments were proposed to mitigate the suffering of the individuals harboring this condition: all of them showing various degrees of toxicity and side-effects (Cole *et al*., 2005; Patel and Kiu, 2016). Even anecdotal use of sulphuric acid, applied directly to the face of an individual in the 17th century, has been reported (van Kleef *et al*., 2009).

In the early and mid-20th century, trichloroethylene (with Plessner in 1915) and stilbamidine (with Napier and Sen Gupta in the 1940s and Woodhall and Odom in the 1950s) became popular; however, their side-effects prevented them being used for long periods (Patel and Kiu, 2016).

Also in the 1940s, with the introduction of diphenylhydantoin, by Bergouignan (based on the hypothesis of Trousseau that TN was a type of sensory epilepsy) and in the 1960s, with carbamazepine by Blom (1962), non-surgical treatment became more feasible, tolerated and efficient, making way for a new era of medical treatment.

Since then, a wide range of similar medications have been tested (e.g. oxcarbazepine, pregabalin, gabapentin, baclofen), despite no formal comparison to placebo have been made (Gronseth *et al*., 2008; van Kleef *et al*., 2009; Bendtsen *et al*., 2019).

Further observation that common medication (i.ex. morphine) were ineffective, added to the fact that TN pain was essentially a form of allodynia (corroborated to imply large Aβ-fibers to the generation of pain) (Bowsher, 1997), would be critical to the development of percutaneous procedures.

3.2.2 Surgical treatment

3.2.2.1 Open Surgery

In 1750, a royal French surgeon, Maréchal, encouraged by the ideas of Nicholas Andres, as well as Veillard and Dussans, proposed severing the infra-orbital nerve as a form of treatment. After a series of unsuccessful procedures, this technique was abandoned (Stookey and Ransohoff, 1959).

In the 18th century, after the discoveries of Charles Bell brought enlightenment to the medical community, a first attempt to surgically treat the malady by accessing the gasserian ganglion was performed by John Murray Carnochan in 1858: a transmalar neurectomy of the second trigeminal division at the *foramen rotundum* was performed with success (Tubbs *et al*., 2010).

William Rose, in 1890, and Andrews in 1891, working separately, described the first ganglionectomy by an infratemporal approach (Stookey and Ransohoff, 1959), severing the maxillary and mandibular divisions at its respective *foramina* and following posteriorly to the GG. However, the approach revealed to be toilsome.

In 1891, an approach to the GG through a transcranial route was described (Stookey and Ransohoff, 1959). This middle fossa, intradural procedure allowed better access to the more proximal structures to perform the rizothomy, but possessed the inconvenient of possible cavernous sinus laceration in the attempt to do the ganglionectomy, which rendered the interruption of the surgery.

Two years later, Frank Hartley and Fedor Krause independently described a subtemporal extradural ganglionectomy which became known as the Hartley-Krause approach. A modification of the technique by Cushing in 1900 reduced mortality to 5% (Cole *et al*., 2005) since he advocated a more basal temporal transcranial route, which led to less intraoperative bleeding and temporal lobe retraction.

Despite their initial success, the approach to the ganglion was not very specific and total rizothomy was the rule: full-face anesthesia frequently complicated with corneal ulceration due to first division lesioning, and masticatory weakness due to third division sectioning. This led to modification and refinement of the technique by Spiller and Frazier in 1901, who, disregarding the GG, selectively severed the pre-ganglionic rootlets and described the preservation of the ophthalmic division and masticatory motor branches (Dandy, 1929) developing the partial sensory rizothomy (PSR). In 1959, Stookey and Ransohoff published the result of 700 PSR done over thirty years: 92% of the patients were pain free, 8% had facial palsy and 30% presented paresthetic symptoms. Gardner also published impressive results: up to 99% of patients remained pain-free (Gardner, 1962) and with acceptable risks, with the Spiller-Frazier procedure

In 1925, Walter Dandy, in an attempt to develop a less time-consuming and motor-preserving procedure, modified the middle fossa approach to a posterior fossa

one through a suboccipital craniotomy, associated with complete sensory rizothomy. He then, experimenting with partial rizothomy, achieved good results and preservation of skin sensation (of note, it is hypothesized that the rootles related to the ophthalmic division were spared because of technical difficulty, since through this approach they are located more medially and cannot be easily severed). Moreover, the risk of facial paralysis and blood loss were significantly lowered with this approach. In a series published in 1929, Dandy also suggested what would become the hallmark of the physiopathology: neurovascular compression by the superior cerebellar artery at the root entry zone. Even with this discovery, he continued to perform the selective rizothomy. Despite his enormous contribution (Dandy, 1932, 1934) with interesting results and intraoperative findings, the Spiller-Frazier procedure remained the gold-standard for treating TN for almost 50 years, since Dandy stated that his procedure was not proven to be better than the aforementioned one (although he himself abandoned it and continued using his own). As of interest, some blame the Dandy-Cushing feud for the lack of widespread publicity of Dandy's Work.

In 1967, Jannetta, an enthusiast of the routine use of the surgical microscope, started exploring the nerves of the posterior fossa, using the approach described by Dandy, reliving interest in open surgery. His observations in 100 patients submitted to surgery were published in 1976 (Jannetta, 1976) where he could confirm vascular compression on the Obersteiner-Redlich zone of the fifth nerve causing demyelinizition. He also stated that mitigation of pain in the post-operative period had relation to occurrence of intra-operative nerve trauma. He recommended that the vessel deforming the trigeminal nerve should be moved and secured with a synthetic

sponge. Since non-destructive technics were less successful than destructive ones, the surgical community failed to accept the technique until multiple reports of encouraging results started to be published (Apfelbaum, 1977; Bederson and Wilson, 1989; Barker *et al*., 1996).

Following a series of excellent outcomes, microvascular decompression (MVD) became the gold-standard in treating TN patients, especially in cases with proven pre-operative nerve deformity caused by vascular anomaly (Barker *et al*., 1996). It is expected that MVD led to 95% of relief and a rate of recurrence of 1% per-year (Tatli *et al*., 2008; Kundu and Rolston, 2018).

3.2.2.2 Chemoneurolysis

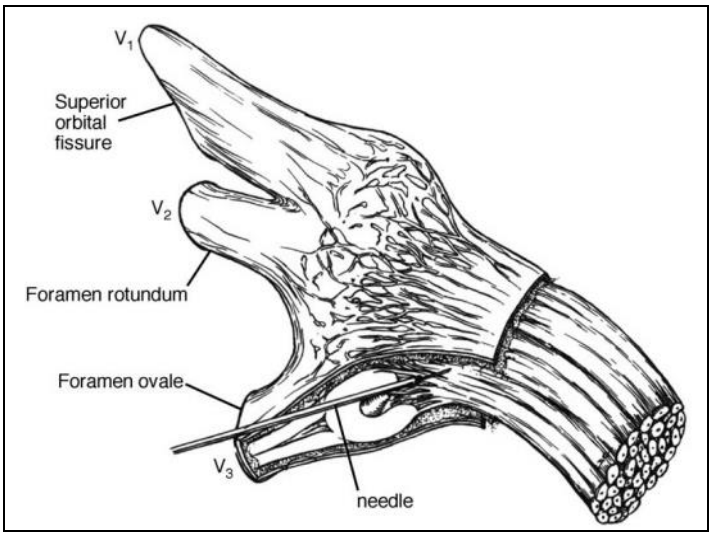
As mentioned before, the imputation of the disease to the trigeminal nerve incited the development of a number of techniques aiming at several degrees of nerve destruction in order to reduce skin sensation and, therefore, defuse the triggers of pain attacks. The excitement emerged by the results of destructive procedures to the GG and pre-ganglionic rootlets through an open approach stirred up the possibility of less invasive ablative ones: peripheral and percutaneous.

The first destructive procedure through a less invasive approach was done with chemoneurolysis in the late 19th century, when Bartholow in 1876 and Neuber in 1883 applied chloroform and osmic acid, respectively, to the nerve trunks in the face. Later, in 1888, Pitres and Vaillard conducted animal experiments with alcohol administration to nerve trunks and evaluating its effects on sensitive and motor functions, leading to the broad use of this chemical agent in treating patients (Stookey and Ransohoff, 1959).

In 1904, Schloesser introduced peripheral chemoneurolysis using alcohol injection into peripheral nerves. Due to short-lasting effects, more toxic agents were progressively researched. In 1907, Wright applied osmic acid into the GG through an open procedure (Stookey and Ransohoff, 1959).

In 1940, Harris published results from 30 years of percutaneously injecting alcohol into the GG, although a high number of them required repeated procedures until anesthesia was achieved. Despite the low mortality rate, the procedure often complicated with dysesthesia, *Herpes simplex* infection, hyperesthesia, keratitis, masticatory weakness (which took 3 months to resolve) and loss of taste. It is stated that the main limitation of the use of alcohol was its broad spread through the cisterns causing multiple cranial nerves deficiency (Cole *et al*., 2005).

The description of the *foramen ovale* puncuture by Härtel (1914), recommendation of the use of X-ray to precisely locate the tip of the needle in the GG (Pollock and Potter, 1916; Putnam and Hampton, 1936; Stookey and Ransohoff, 1959) and the development of an insulated needle that used electric stimulation for localization by Selverstone (Pollock and Potter, 1916; Putnam and Hampton, 1936; Stookey and Ransohoff, 1959) gave way to the safe delivery of substances in a more precise fashion (Figures 1, 2 and 3).



Fonte: Liu *et al*. (2007)

Figure 1 - Figure depicting the location of the needle in the trigeminal ganglion through the *foramen ovale* approach

Figure 2 - Anatomical model showing the trajectory of the percutaneous approach to the trigeminal ganglion through the *foramen ovale*

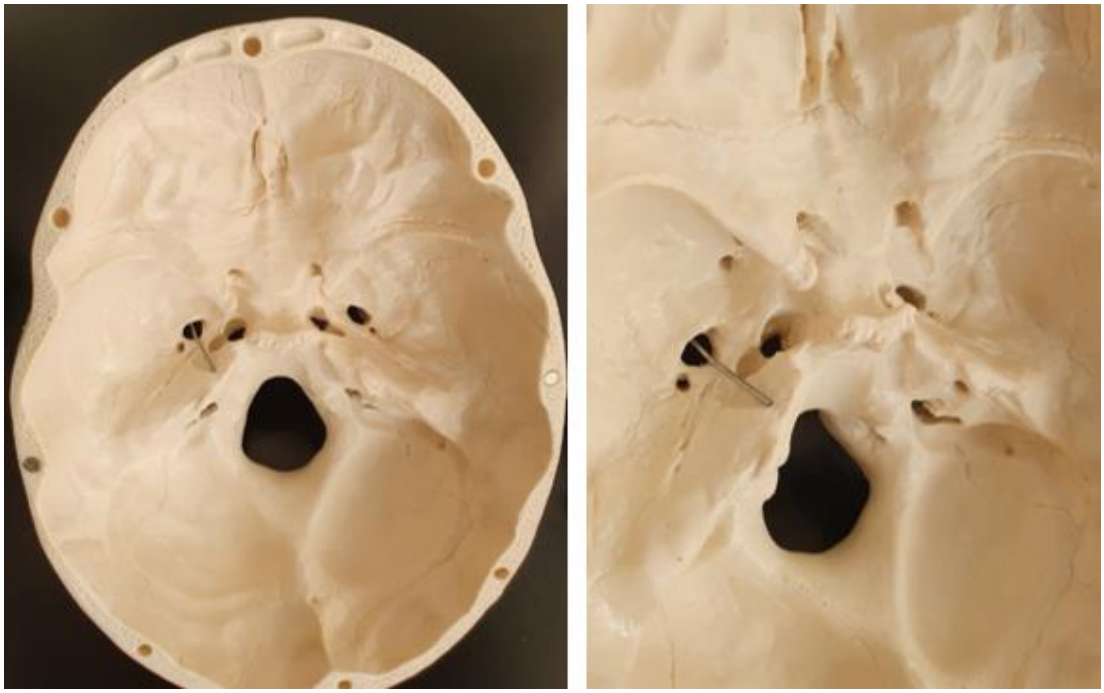


Figure 3 - Position of the needle through *foramen ovale,* from an intracranial view

Therefore, chemoneurolysis with alcohol was used for most of the 20th century, until glycerol was discovered at random (Hakanson, 1981). The latter agent was delivered in the retrogasserian region and, albeit the high recurrence rate, sensitivity sequelae was low. Due to its reasonable performance, percutaneous retrogasserian chemoneurolysis is still largely used.

The possibility of reaching the trigeminal ganglion and the pre-ganglionic rootlets gave rise to the pursuit of more advanced methods of ablation: more profound effects (reduced rates of recurrence) with less side-effects (avoidance of masticatory muscles weakness, intolerable paresthesia, painful anesthesia, keratitis and corneal ulceration). The principle of fiber destruction using chemical agents stimulated the development of other technics with the same purpose.

3.2.2.3 Percutaneous procedures

- Radiofrequency

The first physical method attempt was described by Rethi in 1913 (Wilkins, 2002). He applied electrocoagulation of the Gasserian ganglion. Followed by Kirschner in 1931 (Kirschner, 1963), both treated patients using Bovie, a monopolar cautery, with an insulated needle.

Overtime, more selective methods of fiber destruction were developed in association with modern anesthetic procedures that allowed the surgeon to awake patients and examine the areas of hypoalgesia (Schurmann *et al*., 1972).

In 1974, Sweet and Wepsic applied radiofrequency thermocoagulation of the preganglionic rootlets instead of electrocoagulation to the trigeminal ganglion, in order to overcome the frequent complications, for instance, blindness, ocular palsy and corneal ulceration (White and Sweet, 1969). Since radiofrequency thermocoagulation was deemed capable of preserving large fibers, skin sensation could be preserved (Letcher and Goldring, 1968; Frigyesi *et al*., 1975). The technique involved controlled coagulation by a radiofrequency generator and temperature control by a thermistor, associated with a potent short-acting sedative and electrical stimulation to help place the electrode in the right targeted division. Modification throughout the years were implemented and the use of neuroleptic anesthesia allowed aweakening the individuals and testing skin sensation. In 1996, Tew and Taha encouraged the use of curved thermistor in order to achieve even more selective lesions.

- Compression neurotomy

In 1952, Palle Taarnhøj, modifying the Spiller-Frazier technique, gave rise to the basis of the Mullan technique: he used the middle fossa intradural subtemporal approach in order to decompress the *dura mater* over the trigeminal ganglion (Taarnhøj, 1954, 1956), a procedure often called gangliolysis. Of the 70 treated patients, it was stated that more than half presented with remission and only 9 cases recurred, with no complications. Pudenz in 1952 (Stookey and Ransohoff, 1959) and Shelden *et al*. in 1955 also published decompression approaches, but to the second and third trigeminal divisions around the *foramina*.

Gardner and Miklos published a report of 112 individuals in 1959, known as the Cleveland series (the latter, known as the Copenhagen series), with 62% of excellent results. His technique was slightly different: after the dura being cut, the rootlets were gently brushed with cottonoid, causing a mild intra-operative nerve trauma. He stated that the compression, due to any abnormality present in the region, could be the cause of myelin loss. The relief of symptoms related to surgical trauma were also noted by Shelden *et al.* (1955, 1960) and Graf (1963). Although the rate of sensibility disturbance was low, the rate of recurrence was about 25%.

Based on these findings, Mullan and Lichtor (1983) introduced a percutaneous technique in 1978 that used a Fogarty catheter in order to mildly traumatize the trigeminal ganglion and pre-ganglionic rootlets. The catheter was placed in the TG and insufflated with a contrast agent until a pear-shape of the balloon, confirmed with fluoroscopy, was obtained. The compression was maintained for 3 to 10 minutes.

Some modifications to the original technique have been described but mainly regarding volume of the balloon, duration of compression, type of anesthesia and type of stylet (preferably blunt in order to avoid major vascular injury to the internal carotid artery in the *foramen lacerum*) (Brown *et al*., 1996). Although the technique possesses a 60% rate of facial numbness and 15% of masticatory weakness (that usually resolved in 3 to 12 months), its major complication is intraoperative cardiovascular event, namely bradycardia. In 2010, Tibano *et al.* (2010) stated that the ganglionic block with local anesthetic, preceding the balloon compression, reduced those effects.

- Contributions from University of Sao Paulo

Some unpublished data, minutely described in Dr. Manoel Jacobsen Teixeira's thesis, in 1984, who is an important researcher in TN, provides important aspects of University of Sao Paulo contribution, with Dr. Portugal's experience with partial ganglionectomy and Dr. Tenuto's works with retrogasserian fascicular sectioning (Teixeira, 1984).

4 METHODS

4.1 Patients

The individuals included in this study had the following characteristics: aged 18 years or older; primary (not-secondary) TN (despite the term primary is not present in the current classification criteria, it is used here to group classical and idiopathic cases) (Cruccu *et al*., 2016; Headache Classification Committee, 2018); no major signs of trigeminal neuropathy on examination; refractory to medical treatment (no pain control or uncontrolled side effects with the maximum tolerated dosage of conventional medication – carbamazepine, phenytoin, oxcarbazepine or baclofen – over the previous year, at least) (Wiffen *et al*., 2014) with involvement of second or third trigeminal division and no previous surgical procedure. Enrollment occurred between May 2015 and December 2018. The exclusion criteria were: involvement of the first trigeminal division or trigeminal neuropathy, previous surgery and/or procedure, patients who refused to participate or had difficulty in understanding the study protocol (Chart 3).

Chart 3 - Inclusion and exclusion criteria used in the present study

Inclusion Criteria 1. Diagnosis of Primary Trigeminal Neuralgia 2. Refractory/Intolerable medical treatment 3. Pain restricted to second or third trigeminal division 4. No previous surgical treatment
Exclusion Criteria 1. Secondary Trigeminal Neuralgia/Trigeminal Neuropathy 2. Pain restricted to the first trigeminal division 3. Refuse to participate 4. Unable to comprehend the questionnaires 5. Previous surgery and/or procedure

4.1.1 Patients

During study period, 87 patients were assessed for eligibility. After applying the inclusion and exclusion criteria, 33 were available for the interim analysis (25 females; 62.18 ± 9.4 years old) (see CONSORT flow-chart – Figure 4): 57.6% with the mandibular division affected and twenty-one with right-sided TN. Table 1 shows the subjects' characteristics and demographics, along comparisons between the groups. If patients failed to attend more than 20% of the visits, they were excluded from study protocol.

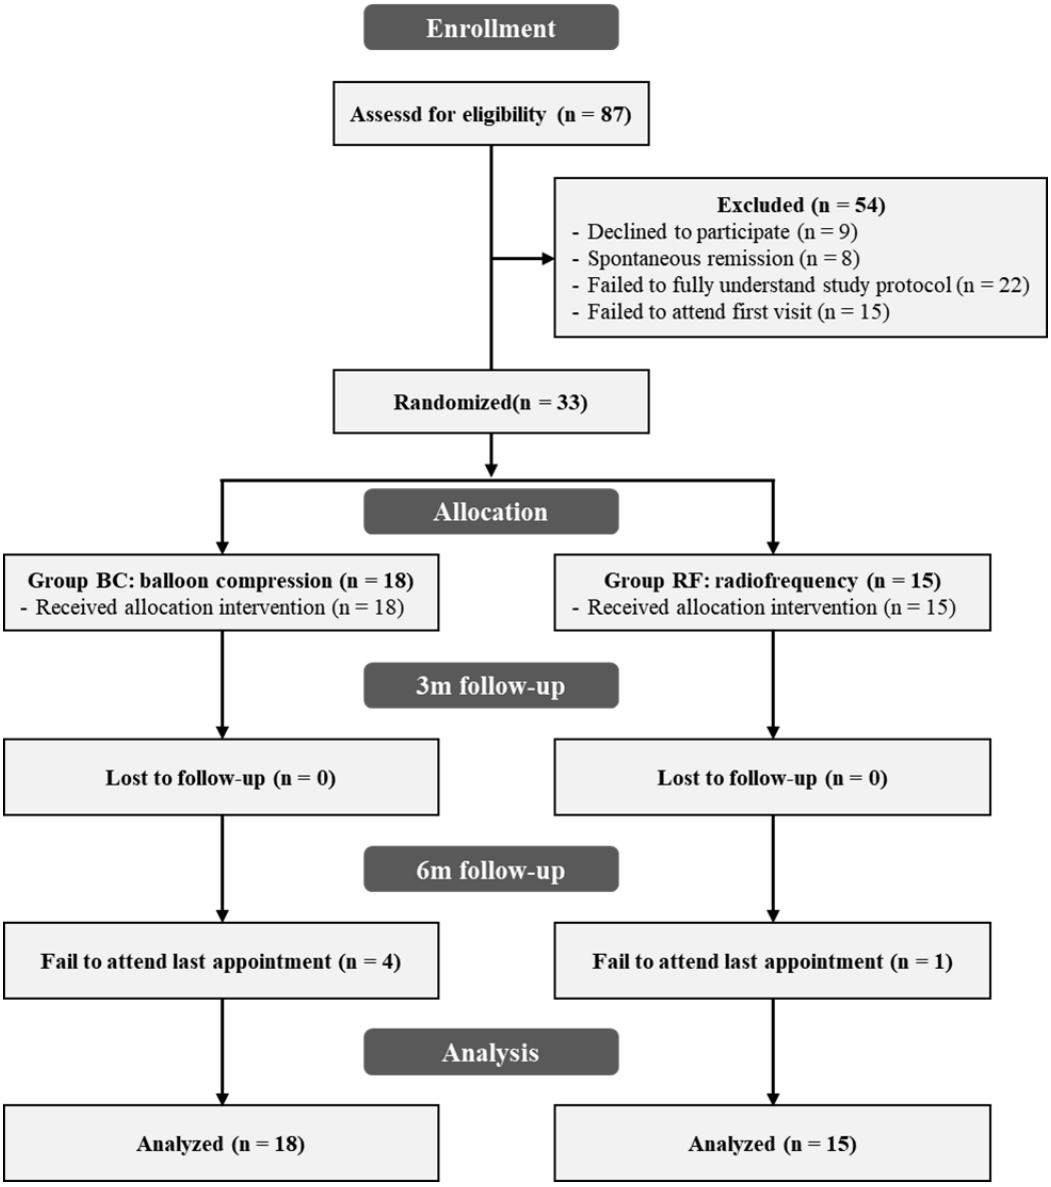

Figure 4 - CONSORT flowchart of the present study

Table 1 - Demographics and pain characteristics of all patients and subgroups

Characteristics		Total (33)	Group 1 (BC) (n=18)	Group 2 (RF) (n=15)	*p*
Age (in years)		62.18 ± 9.4 (40-78)	65 ± 9.42 (45-78)	58.8 ± 8.47 (40-71)	0.058
Sex	Male	8 (24.2%)	5 (16.7%)	5 (33.3%)	0.266
	Female	25 (75.8%)	15 (83.3%)	10 (66.7%)	
Skin colour	White	26 (78.8%)	14 (77.8%)	12 (80%)	0.458
	Brown	6 (18.2%)	4 (22.2%)	2 (13.3%)	
	Black	1 (3%)	0	1 (6.7%)	
Marital status	Maried	17 (51.5%)	9 (50%)	8 (53.3%)	0.772
	Divorced	6 (18.2%)	3 (16.7%)	3 (20%)	
	Widow	6 (18.2%)	4 (22.2%)	2 (13.3%)	
	Single	3 (9.1%)	2 (11.1%)	1 (6.7%)	
	Stable union	1 (3%)	0	1 (6.7%)	
Trigeminal Division	Second	14 (42.4%)	7 (38.9%)	7 (46.7%)	0.653
	Third	19 (57.6%)	11 (61.1%)	8 (53.3%)	
Laterality	R	21 (63.6%)	14 (77.8%)	7 (46.7%)	0.064
	L	12 (36.4%)	4 (22.2%)	8 (53.3%)	
Other previous non-trigeminal pain syndrome		18 (54.5%)	12 (66.7%)	6 (40%)	0.126

The values are presented as mean ± SD (range).
BC: balloon compression; RF: radiofrequency. R: right; L: left. Significance set at $p < 0.05$.

4.2 Location and Recruitment

This study was conducted at the pain center outpatient clinic of Hospital das Clínicas, University of São Paulo. Patients with the diagnosis of TN were referred from regional neurology and pain clinics in the State of Sao Paulo (approx. 44 million inhabitants) and were screened for participation by one of the researchers, either by phone or at in-person screening visits. The specific sites of each stage of the study is detailed below (Chart 4).

Chart 4 - Physical sites used in the study

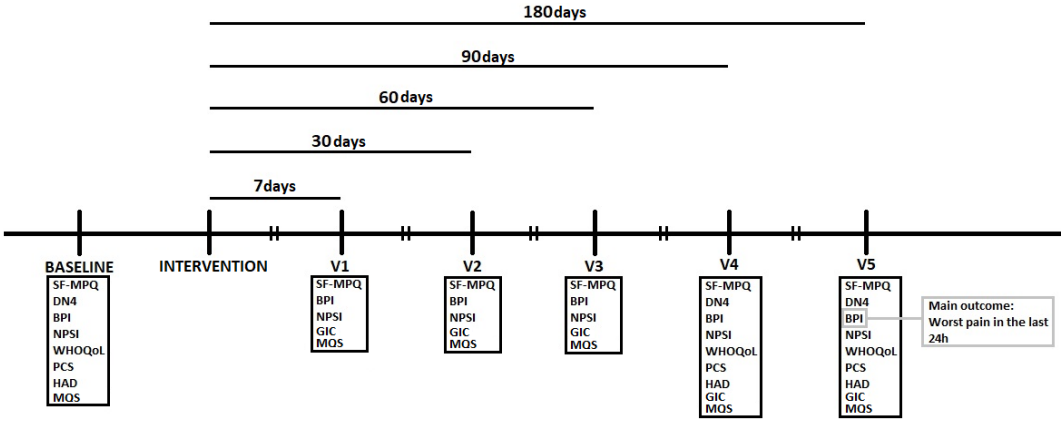
Stage	Location
Screening and recruitment	Outpatient pain clinic
Pre- and post-operative evaluations	Neurophysiology and Pain Center
Procedure	Surgical center of Instituto de Psiquiatria

4.3 Study design

A prospective double-blinded (subjects and rater) head-to-head randomized clinical trial was designed to compare the effects of BC and RF on the trigeminal ganglion for treating TN. Analysis were made on intention-to-treat basis. Since there was a paucity of formal clinical trials on ablative surgery for NT (Zakrzewska and Akram, 2011), no formal sample size calculation could be performed beforehand. Therefore, we designed a pragmatic clinical trial: we used a convenience sample of TN patients based on the sample size of previous studies (n = 30 per arm), in order to assess equivalence between arms (Erdine *et al.*, 2017; Zakrzewska and Akram, 2011).

A pre-planned interim analysis, previously approved by the institutional review board (IRB), was envisaged when half of the total sample was reached in both groups, in order to access safety and pain control data, and to assess whether there was any need to revise the number of subjects needed. The interim results were analyzed by an external research panel and one of the following decisions would be made: 1 – to stop the trial because significant differences between the arms had already been discerned; 2 – to stop the trial because it was futile to continue; or 3 – to pursue the trial with a new sample size calculated based on the information obtained from the first part of the study, with a new sample size target. This interim analysis was preplanned and was set forth in the registration document for this trial, which is available in the online open trial repository (clinicaltrials.org; NCT 02427074) (Attachment B).

After inclusion, patients were conducted as depicted in the Figure 5.



SF-MPQ: Short-Form McGill Pain Questionnaire; DN4: Douleur Neuropatique 4; BPI: Brief Pain Inventory; NPSI: Neuropathic Pain Symptom Inventory; WHOQoL: World Health Organization quality-of-life questionnaire; PCS: Pain Catastrophizing Scale; HADS: Hospital Anxiety and Depression scale; MQS: Medication Quantification Scale; GIC: Global Impression of Change.

Figure 5 - Scheme depicting follow-up and scheduled appointments

4.4 Primary outcome measurement

The primary outcome of the present study was assessed using the third item of the Brief Pain Inventory (BPI): numeric ranking scale (from zero to 10) of the worst pain in the last 24-hours.

4.5 Secondary outcome measurement

Secondary outcomes were measured using the specific questionnaires related below. Despite not being objective of analysis in the present thesis, data was collected for future studies and thesis aiming side-effects and prediction of response based on individual pain features, socioeconomics and psychological profile.

4.6 Randomization

Individuals were randomly allocated to either balloon compression or radiofrequency thermocoagulation at a 1:1 proportion. An electronic software (available at www.randomizer.org) was used to perform the randomization in blocks of 4.

4.7 Blinding

Blinding of the subjects was ensured by informing patients they would undergo one of two traditional percutaneous techniques for treating the symptoms of TN. The responsible for randomization and data plotting did not participate in the surgical procedure nor the postoperative appointments; moreover, had no access to the patients' intraoperative or outpatient visit records.

A standardized questionnaire was used to assess the blinding of the study, which was filled out at the end of the trial. It was composed of four questions: 1 – How much pain did you experience during the surgical procedure, on a numerical rating scale from 0 (no pain) to 10 (worst pain)?; 2 – Would you be able to tell which treatment you were receiving (yes/no)?; 3 – If so, which group do you think you were in (group 1/group 2)?; 4 – Would you be willing to undergo the procedure again if it was offered to you (yes/no)? (Rocha *et al*., 2014).

4.8 Ethics

The Institutional Ethics Committee approved this protocol (CaPPesq 1180/09, Attachments C, D and E). A consent form was obtained for all patients (Attachment F).

4.9 Safety

All percutaneous procedures were performed in a Surgical Suite by the same surgeon and under monitorization, followed-up closely by an independent anesthesiology staff member.

4.10 Instrumentalized evaluation

The subjects were evaluated using specific questionnaires.

4.10.1 Brief Pain Inventory

This consists of a 9-item questionnaire that includes a pain severity index (mean of questions 3-6, with a numerical rating scale that ranged from 0 to 10, such that the lower the score was, the lower the pain level was) and measurement of the interference of pain with daily activities (mean of questions 9A-9G, with a numerical rating scale that ranged from 0 to 10, such that the lower the score was, the less the interference was. In addition, this questionnaire can assist in gathering information about medications and dosage currently used by the subjects. The primary outcome used in the present study was the third question of this questionnaire, asked at the last evaluation (180 days after the procedure): “What was your worst pain level over the last 24 hours?” (Daut *et al*., 1983; Ferreira *et al*., 2011) (Appendix A).

4.10.2 McGill Pain Questionnaire - short form (SF-MPQ)

This questionnaire contains 15 descriptors of pain within three aspects and qualities of pain: sensory-discriminative, affective-emotional and cognitive-evaluative. The total score possible is 15, and each item is binary: present or absent (Melzack, 1987; Ferreira *et al*., 2013) (Appendix B).

4.10.3 Douleur Neuropatique 4 questionnaire (DN4)

This is a 10-item scale that evaluates the possible presence of a neuropathic component of pain. The screening is positive for scores ≥ 4 (Bouhassira *et al*., 2005; Santos *et al*., 2010) (Appendix C).

4.10.4 Neuropathic Pain Symptom Inventory (NPSI)

This is a validated instrument that encompasses various aspects of neuropathic pain. It is composed of 10 items that are presented as numerical rating scales with a range from 0 to 10, each referring to a specific feature: superficial spontaneous pain (question 1), deep spontaneous pain (mean of questions 2 and 3), paroxysmal pain (mean of question 5 and 6), evoked pain (mean of questions 8, 9 and 10) and paresthesia/dysesthesia (mean of questions 11 and 12). The possible total score is 100. The temporal aspects of continuous and paroxysmal pain are assessed in question 4 (duration of spontaneous pain over the last 24 h) and question 7 (number of pain attacks over the last 24 h). NPSI was also used here to evaluate non-paroxysmal pain: scores of 4 or higher than the mean in the first domain (superficial spontaneous pain) and second domain (deep spontaneous pain) were considered to

represent continuous pain (Bouhassira *et al*., 2004; de Andrade *et al*., 2011) (Appendix D).

4.10.5 World Health Organization quality-of-life questionnaire – brief from (WHOQoL-BF)

A short 26-item version of a full 100-item questionnaire which evaluates physical, psychological, social relationships and environmental relationships domains of quality of life. The higher the scores are, the better the quality of life is (Development, 1998; Fleck *et al*., 2000) (Appendix E).

4.10.6 Pain Catastrophizing Scale (PCS)

This is an instrument that evaluates the emotional distress and disability that pain causes in subjects. It consists of a 13-item scale, on which each item can be scored from 0 to 4 each, thus giving a total score of 0 to 52. The higher the score is, the more elevated the distress is (Sullivan *et al*., 1995; Sehn *et al*., 2012) (Appendix F).

4.10.7 Hospital Anxiety and Depression Scale (HADS)

This is a 14-item questionnaire (7 items for anxiety and 7 for depression symptoms, with scores ranging from 0 to 3 each) that aids in screening for mood disorders, with total scores from 0 to 21 for anxiety and for depression. Higher scores suggest depression/anxiety (Zigmond and Snaith, 1983; Pais-Ribeiro *et al*., 2007) (Appendix G).

4.10.8 Global Impression of Change (GIC)

This is a scale used by the patient (p-GIC) and evaluator (c-GIC) to rate the global evolution of their pain since the first visit. In both cases, the GIC included seven ranks ranging from 1 to 7 (1 = very much improved, 2 = moderately improved, 3 = slightly improved, 4 = no change; 5 = slightly worsened; 6 = moderately worsened; 7 = very much worsened) (Dworkin *et al*., 2005; de Andrade *et al*., 2011) (Appendix H).

4.10.9 Medication Quantification Scale version 3 (MQSv3)

This is a standardized scale for quantifying the medications used by the patient and their dosages. It provides a weighted final score for the "medication burden" (Harden *et al*., 2005).

4.11 Procedures

4.11.1 Anesthetic procedure and *foramen ovale* puncture

All patients fasted for six hours before the intervention. An intravenous access was placed and prophylactic antibiotic was given 1 hour before surgery. The anesthetic routine for the BC comprised administration of intravenous (IV) propofol (2.5 mg/kg), IV fentanyl (50 to 150 mcg), muscle relaxant (rocuronium, 1 mg/kg) and placement of endotracheal catheter.

The subjects received atropine (0.25 mg), and sedation was maintained with sevoflurane 1-1.2 MAC until the end of the procedure. For RF, the patients received mild sedation with propofol and fentanyl and an O_2 catheter was placed. They were

then awakened for skin sensory evaluation. Under complete aseptic conditions, the skin over the needle entry-point was infiltrated with 1% lidocaine. The patient was placed in the supine position with the head perpendicular to the horizontal plane. The entry point was set as 2.5 to 3 cm laterally to the labial commissure, depending on whether the target was the third (mandibullary) or second (maxillary) trigeminal division, respectively. The planes used to access the *foramen ovale* had previously been described (Härtel, 1914; Tew Jr. and Keller, 1977; Mullan and Lichtor, 1983): one that passes through the ipsilateral pupil and another one 3 cm anteriorly to the tragus, also ipsilaterally. Using radioscopic imaging (Siemens®, Siremobile, Erlenzen, Germany), the puncturing of the *foramen ovale* was confirmed (using the clival line as the reference for the second trigeminal division; and 5 mm anteriorly to the clival line for the third trigeminal division) (Figures 6 and 7).

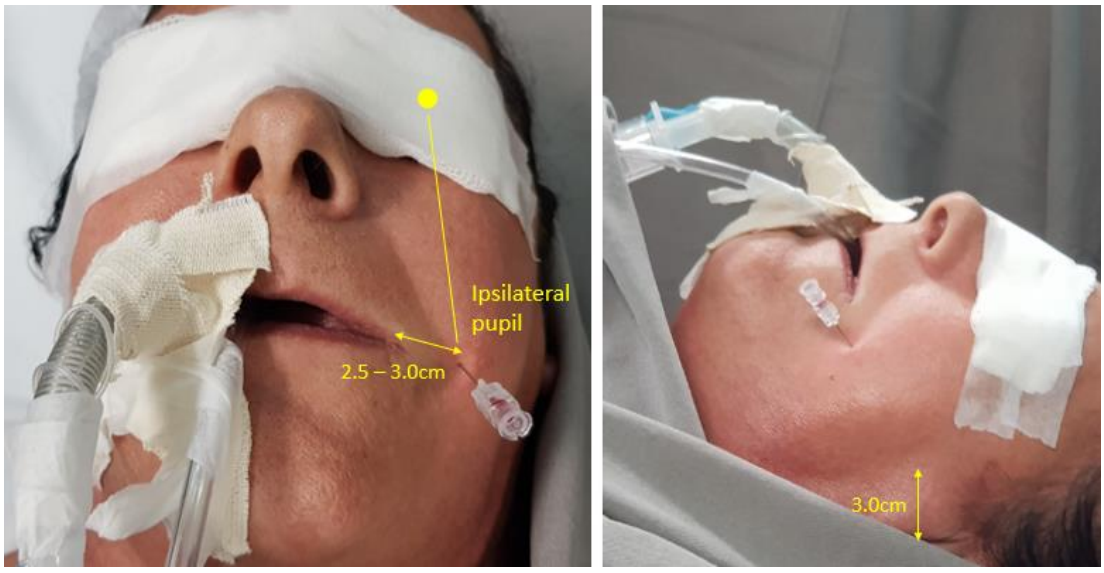


Figure 6 - Topographic references for *foramen ovale* puncture

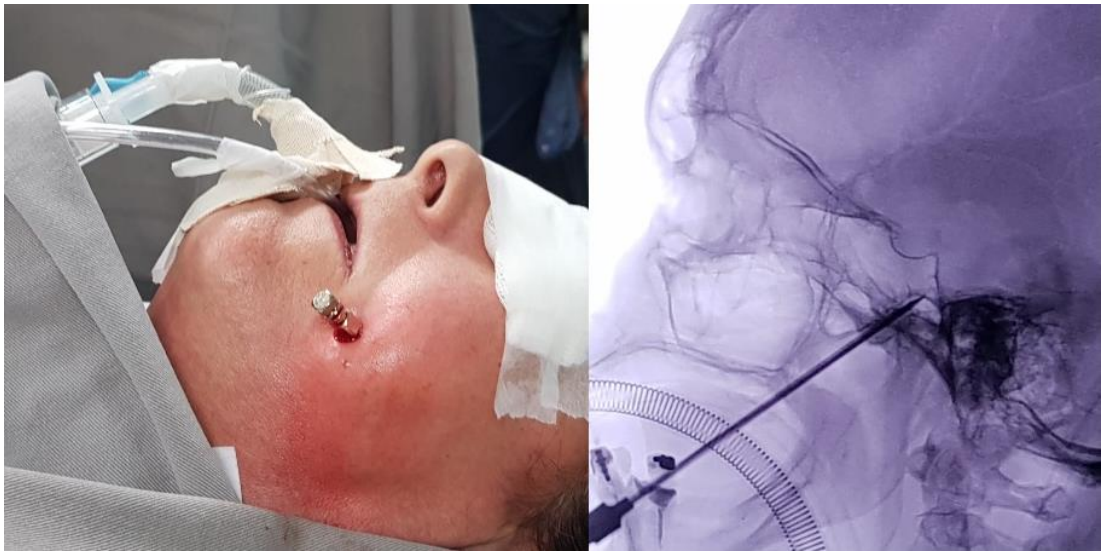

Figure 7 - LEFT: Photograph of the percutaneous approach to the trigeminal ganglion; RIGHT: respective fluoroscopy confirming the position

4.11.2 Balloon compression

For the BC technique, after puncturing the *foramen ovale* with a 14G needle (BR R Becton Dickinson, Juiz de Fora, MG, Brazil, Figure 8), 1% lidocaine was administered to the trigeminal ganglion until facial anesthesia was attained. Then, a 4F Fogarty catheter (American Edwars Laboratory, USA, Figure 8) was placed in the trigeminal cistern and insufflated with 0.7 mL of the contrast agent Iopamiron® (125R, Schering, São Paulo, Brazil) until the balloon assumed a "pear shape" (Figure 9) on the C-arm. Compression of the trigeminal division by the inflated balloon was maintained for 120 seconds. At the end, the balloon was deflated and the catheter and needle were removed. Mechanical compression was applied to the point of entry.

Figure 8 - Needle and Fogarty catheter used in balloon compression

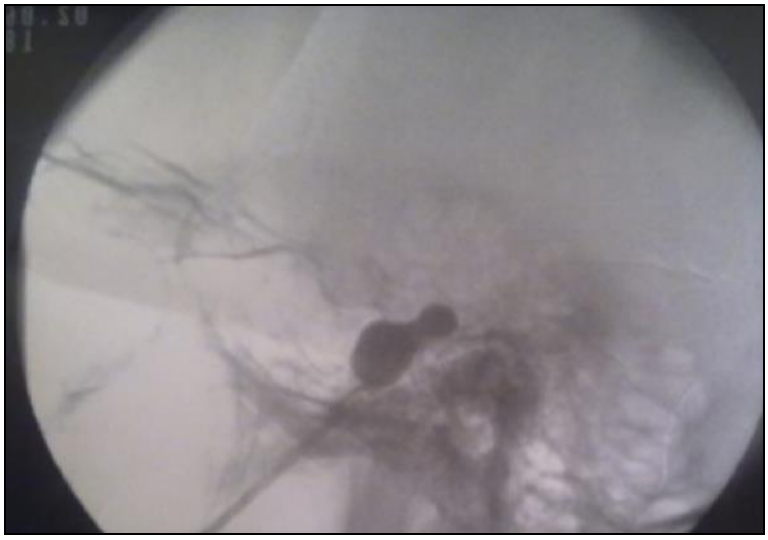

Figure 9 - Fluoroscopic image of the "pear-shape" of the balloon during compression

4.11.3 Radiofrequency thermocoagulation

For the RF technique, after puncturing the *foramen ovale* with the needle, an electrode (Radionics®, 15 cm, insulated, Figure 10) was inserted and connected to a Radionics® generator (RFG-3C Plus, Figure 10). After evaluating the impedance (250 - 300 ohms), the trigeminal division of interest was confirmed through

stimulation (sensory stimulation at 50 Hz and 0.1 to 0.5 V, with the patient awake to describe the area of paresthesia, and motor stimulation at a frequency of 2 Hz and 0.1 to 0.5 V, with the patient asleep, until masticatory movements were observed). After confirming which trigeminal division was to be targeted, we began inducing the thermocoagulation injuries, which was done at 70 °C for 60 seconds. The pinprick sensation was tested and compared to the contralateral side using a safety pin between cycles and this process was repeated until skin anesthesia over the targeted area had been achieved (an average of 2 to 3 cycles were necessary).

Figure 10 - RF electrode and radiofrequency generator utilized

4.12 Missing Data

For patients to be included in the analyses, a minimum of 80% attendance was required and provision of at least 80% of the information at each clinical visit. Data imputation was done by using the last-observation-carried-forward methodology.

4.13 Statistical Analysis

The variables were expressed using absolute values and frequencies (for categorical variables), and means and standard deviations along with minimum and maximum values for continuous variables. The effect of the interventions on the main outcome, i.e. 'worst pain level over the last 24 hours' was assessed using a series of generalized estimation equations (GEE). The measurements at the baseline and at seven, 30, 60, and 180 days after the intervention were evaluated longitudinally, and the fact that all measurements were estimated for the same patient was accounted for.

Since the outcome presented non-normal distribution, its raw numerical values were re-categorized as indicator variables with cutoff points greater than or equal to two, three, five or seven points (in doing this, differences between the procedures that were small and under or above five, could be tracked). These dichotomous values were analyzed through GEE with binomial distribution. The models evaluated the association between the outcome and the two interventions, and differences at the baseline were accounted for.

We reported the results as the predicted means for numerical outcomes and as odds ratios for categorical outcomes, along with 95% confidence intervals (Rutten-van Molken *et al*., 1994). The Kolmogorov-Smirnov test was used to test the normal distribution of variables. For non-normally distributed variables, comparisons between groups were made using the Mann-Whitney test and Pearson's chi-square test. The Student t test was used for normally distributed variables.

For the interim analysis, the sample size for the difference in slopes between the balloon compression and the conventional radiofrequency groups was calculated, to yield a power of 0.8 and detect a difference in slopes of 1.5, with a residual variance of 1 and a significance level of 0.05 (Diggle *et al*., 2002).

Statistical analyses were performed using IBM SPSS (Statistical Package for Social Sciences) v17.0 and R-Project (r-core team REF).

5 RESULTS

5.1 Social-demographic data

Eighty-seven patients were assessed for eligibility. Thirty-three were included for the interim analysis: 57.6% with the mandibular division affected and twenty-one with right-sided TN. Of the total, 25 were females with a mean age of 62.18 ± 9.4 years old. Table 1 shows the subjects' characteristics and demographics included in preplanned interim analyses, along with comparisons between the groups.

5.2 Baseline charactheristics

The two groups showed similar medication usage at the baseline, as depicted by the MQS score (10.63 ± 6.21 for BC; 12.47 ± 4.44 for RF; $p = 0.292$). The pain characteristics at the baseline were evaluated using several questionnaires (Table 2). There was no difference in the total SF-MPQ score between the BC and RF groups (12.89 ± 1.71 and 12.2 ± 2.51, respectively; $p = 0.617$). There was also no significant difference between the groups regarding positive DN4 scores (total score ≥ 4: 88.9% in BC group versus 80% in RF group; $p = 0.639$). In the BPI questionnaire, there was no difference between the groups regarding the worst pain level over the last 24 h (Figure 3), i.e. main outcome of the study (6.94 ± 3.55 and 8.2 ± 3.19, for BC and RF groups respectively; p =

0.292); or in relation to the pain intensity index (4.46 ± 2.68 in BC and 5.08 ± 2.66 in RF; p = 0.526). There was also no difference between the groups regarding pain interference (6.72 ± 2.95 in BC and 6.26 ± 2.61 in RF; p = 0.527).

Regarding the specific pain characteristics analyzed using the NPSI, the two groups presented similar subgroup features (spontaneous superficial pain: 6.28 ± 3.8 and 4.8 ± 4.75, p = 0.362; deep spontaneous pain: 3.39 ± 4.09 and 3.93 ± 4.6, p = 0.876; paroxysmal pain: 5.39 ± 3.87 and 6.53 ± 4.34, p = 0.262; evoked pain: 5.63 ± 3.76 and 5.38 ± 3.37, p = 0.828; and paresthesia/dysesthesia: 4.28 ± 3.41 and 4.6 ± 3.62, p = 0.729; BC and RF group, respectively). Regarding the duration of spontaneous pain, it was less than 1 h for 33.3% of the patients in the BC group and 53.3% in RF group. For 27.8% of the individuals in the BC group and 26.7% in the RF group, there were no pain attacks within the last 24 h, nor was the total score significant (49.28 ± 29.16 in BC group and 51.07 ± 32.89 in RF group; p = 0.857). Furthermore, none of the other features reported (PCS, WHOQoL and HAD) showed any differences.

The values are presented as mean ± SD (range) or n (%).
BC: balloon compression; RF: radiofrequency. SF-MPQ: Short-Form McGill Pain Questionnaire; DN4: Douleur Neuropatique 4 Questionnaire (neuropathic pain present ≥ 4); BPI: Brief Pain Inventory; MQS: Medication Quantification Scale version III; NPSI: Neuropathic Pain Symptom Inventory; WHOQOL: World Health Organization Quality of Life Questionnaire brief form; PCS: Pain Catastrophizing Scale; HAD: Hospital Anxiety and Depression Scale (HAD-A: anxiety symptoms; HAD-D: depression symptoms). Significance is set as $p < 0.05$.

5.3 Primary Objective

Numeric ranking scale over the last 24 hours between each group at six months revealed no significant difference (CI95% 0.6 – 3.84 and -0.64 – 2.24, for BC and RF, respectively). Table 3(a) displays information on the study's main outcome, which was categorized as higher or lower than five. We present data on this outcome and its association with the intervention groups, taking into account all the follow-up measurements up to the 180-day assessment, by using Generalized Estimated Equations (GEE) models. The results were corrected for age and race, and indicated that there were no statistically significant differences between the two groups. A similar pattern was observed when re-categorizing the worst pain level over the last 24 hours into higher or lower than two, three or seven, as depicted in

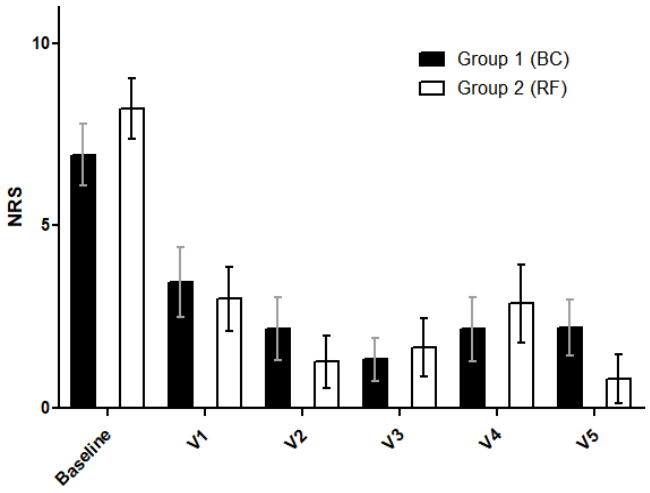
Table 3(b). Despite some change overtime could be observed in each group, this difference did not reach statistical significance. Graphic 1 illustrates the comparison of the worst pain level over the last 24 hours, over time, between the two intervention arms. Patients subjected to BC therapy or RF reported similar pain intensities over the study period. At 180 days after the intervention, the patients in the balloon compression group reported slightly higher levels of pain, compared with those in the radiofrequency group, although no significant difference was observed.

Table 3 - Predicted odds ratio and confidence intervals for the worst pain level over the last 24 hours

	Group 1 (BC) n=18	Group 2 (RF) n=15	*P*
a)			
Worst pain in the last 24 hours above 5[a]	1.12 (0.51, 2.49)	1 [Referent]	0.78
b)			
Worst pain in the last 24 hours above 2[b]	1.07 (0.48, 2.39)	1 [Referent]	0.86
Worst pain in the last 24 hours above 3[b]	1.06 (0.48, 2.33)	1 [Referent]	0.88
Worst pain in the last 24 hours above 7[b]	1.22 (0.51, 2.93)	1 [Referent]	0.66

Comparison of the "worst pain level over the last 24 hours" transformed to a dichotomous variable (a: above 5; b: above 2, above 3 and above 7).
The values are presented as odds ratio (95% confidence intervals). BC: balloon compression; RF: radiofrequency. Significance is set as $p < 0.05$.

Graphic 1 - Numerical rating scale (NRS) of main outcome (worst pain level over the last 24 hours)



Results expressed as mean and standard error between groups, in each appointment.

5.4 Secondary Objectives

Concerning the pain phenotype, patients in the RF group reported more paresthetic symptoms than those in the BC group (2.08 ± 1.99 versus 3.97 ± 1.96, respectively; p = 0.017). Moreover, there was a higher number of RF patients who were completely pain-free (100% of these individuals), compared with the BC group (4.55 ± 0.78 versus 5 ± 0; p = 0.015) at the first assessment (visit 1 at 7 days postoperatively). The paresthesia symptom scores were significantly higher in the RF group at 30 days (V2; p = 0.01), but these symptoms were resolved during the follow-up (V5; p = 0.294). At 90 days (V4), the individuals in the BC group presented lower NPSI total scores (9.61 ± 15.2 versus 15.07 ± 20.75 in the RF group; p = 0.038), but at the last evaluation, this difference was no longer present (p = 0.598).

Patients presenting with continuous pain at the baseline comprised 66.7% of the BC group and 53.3% of the RF group. At the last evaluation, these proportions were 5.6% and 20%, respectively. No difference was noted at either time: p = 0.435 and p = 0.308. Regarding purely paroxysmal pain, at the baseline this affected 16.7% in the BC group and 40% in the RF group. After the follow-up, these proportions were 72.2% and 66.7%, respectively. Again, no difference was observed (p = 0.239 and p = 0.730).

5.5 Pain and Associated Variables

In terms of presence of neuropathic pain using the DN4 questionnaire, 33.3% and 60% of the individuals, respectively in the BC and RF groups, scored 4 or more at 6 months (V5). Although these proportions were lower than at baseline (88.9% and 80% for BC and RF), no difference was observed between groups ($p = 0.126$).

Regarding the pain descriptors using the SF-MPQ, although some reduction over time was observed, no significant difference was found (12.89 ± 1.71 and 12.20 ± 2.51; 3.39 ± 4.23 and 2.20 ± 3.86; for BC and RF at the baseline and last appointment, respectively).

Evaluation of emotional distress and disability using PCS showed total scores at the last appointment of 13.50 ± 15.72 and 11.67 ± 14.40, for BC and RF respectively. These scores were not statistically different.

The medication usage, quantified using the MQS vIII, ranged from 10.63 ± 6.21 to 5.84 ± 6.60 for the BC group, and from 12.47 ± 4.44 to 5.82 ± 6.75 for the RF group, also with no difference between them.

Quality of life and its domains, assessed using WHOQoL did not show any significant differences, despite showing increased scores over time.

The mood symptoms of anxiety and depression, evaluated through the HADS questionnaire, showed improvement over the study period (total scores of 16.83 ± 9.6 and 17.13 ± 8.79 at the baseline and 8.17 ± 6.77 and 10.27 ± 8.67 at the last appointment, respectively for BC and RF). However, no significant difference between the groups could be seen.

5.6 Blinding Assessment

Pain during the procedure was evaluated because this is a possible source of blinding bias. The mean values (ranging from 0 to 10) and standard deviations for BC and RF were, respectively, 1.33 ± 2.06 and 4 ± 2.27 ($p = 0.02$). This revealed that the subjects in the RF group experienced more pain during the intervention than did those in the BC group.

After completion of the protocol, 44.4% of the individuals in group BC reported that they were able to tell which group they had been allocated to, and 66.7% of these individuals guessed it right. In group RF, the proportion was 37.5% for both ($p = 0.35$). When asked if they would be willing to undergo the procedure again if it was offered, the proportions were 55.5% and 50%, for groups BC and RF, respectively. None of these proportions were statistically significant.

5.7 Procedures and Safety

All the patients were discharged from hospital within 24 hours after the intervention. There was no difference in postoperative pain between the groups: patients in both groups experienced new pain after the procedure. However, this pain was self-limited and was relieved with common painkillers (the intensity and duration were similar).

5.8 Effect and Sample Size

The preplanned interim analysis was performed at the time when each arm reached half of the scheduled number of subjects, in order to evaluate the safety and effect size of the protocol. The power of the present study was 4.7%. Therefore, to show a real difference between the groups (with a power of 80% and a significance level of 0.05), if there truly was any difference whatsoever, 1500 individuals per arm would be needed, thereby rendering the value of the interventions doubtful. A calculation to update the sample size, so that it would be capable of showing any difference that might exist between the groups, using generalized estimated equations in future studies, indicated that 1457 individuals per arm would be needed. Therefore, the study was halted because it would have been futile to continue.

6 DISCUSSION

Here, we report the results from the first attempt to prospectively compare the two most commonly used percutaneous interventions for TN using a randomized double-blind trial. After a preplanned interim analysis, the study was halted because it would have been futile to continue. No significant effects were found in relation to the primary outcome, i.e. pain intensity after six months using the BPI questionnaire.

The sample size used in the present study was based on previous reports of the effect size in surgical TN trials (Zakrzewska and Akram, 2011). However, a post-hoc power analysis calculated using the effect sizes obtained in the present study suggested that, if a real difference in pain relief should exist between the two interventions, a clinical trial would require a large number of participants in each arm. This sample size is higher than the sum of all the patients enrolled in all TN trials performed to date, including pharmacological trials (Broggi *et al*., 1990; Taha and Tew, 1996; Skirving and Dan, 2001; Teixeira *et al*., 2006; Koopman *et al*., 2011). For example, the largest series published enrolled 1,600 patients over 25 years, which is approximately the number needed for just one arm (Kanpolat *et al*., 2001).

Although TN is a neuropathic pain syndrome, its paroxysmal and episodic nature imposes some obstacles in quantifying pain, as depicted by the low positivity of the DN4 at baseline. Therefore, the use of alternative instruments (eg., NPSI) may be helpful to characterize the other pain features such as its temporal pattern

(paroxysmal or continuous) and number of paroxysms per day. This is in accordance with an issue repeatedly stated in TN research: which is the best method to better evaluate a neuropathic pain that is episodic in nature. To our knowledge, this is the first study to use specific questionnaires to overcome this hindrance. Interestingly, some differences in secondary outcomes were observed between the groups: individuals receiving RF experienced more paresthetic symptoms after the procedure despite presenting no pain attacks at V1. This suggests that this symptom after percutaneous thermocoagulation may be expected as a side-effect but it will most likely subside after 4 weeks. On the other hand, the patients who underwent BC presented lower total NPSI scores at V4. At the last evaluation, the previously observed differences disappeared. We also used specific NPSI scores to evaluate occurrences of non-paroxysmal facial pain: no difference was observed between the baseline and the last appointment, despite a reduction over time.

The decision regarding which treatment to offer patients with trigeminal neuralgia has been an issue of great debate for a long time. Although adequate pain control has been achieved through use of carbamazepine (Campbell *et al*., 1966), some patients may suffer from unsustainable side-effects or may not reach satisfactory pain-attack control (Fields, 1996; Casey, 2005; Cruccu *et al*., 2008). Therefore, thorough evaluation of individuals and images are paramount in deciding which intervention should be proposed.

Percutaneous procedures have been used for over four decades without clear evidence regarding which of these is most effective for controlling TN pain. A number of large series of patients who underwent ablative interventions is available in the literature, but the outcomes have often been measured using different

instruments that exhibit poor clinical relevance. Moreover, the pain characteristics are often not considered in a comprehensive manner: for instance, number of pain attacks, intensity of pain attacks, reduction of medication burden, non-paroxysmal pain, etc (Attachment A - summarizes the largest and most important case-series and outcome measurements).

Taking into account procedure-related risks and technical difficulties, it appears that ablative procedures are preferred over MVD for a number of reasons (Cruccu *et al*., 2008; Gronseth *et al*., 2008): simplicity, outpatient management and a low profile of severe side effects. In addition, the outcomes of the latter appear to be better only in high-volume centers (Kalkanis *et al*., 2003). Historically, individuals often underwent percutaneous ablative procedures for the above mentioned reasons and because of the need for a learning curve for MVD (Broggi *et al*., 1990; Teixeira *et al*., 2006; Spatz *et al*., 2007; Zakrzewska and Linskey, 2009; Koopman *et al*., 2011; Jones *et al.*, 2019). Since the time when ablative procedures became part of the armamentarium of treatment options for NT (Sweet and Wepsic, 1974; Mullan and Lichtor, 1983), the procedures most used have been BC and RF. Despite their safeness, evaluation of the pain profile has not been formally addressed; the most commonly used outcome is recurrence rate; however, there is no well-established instrument for its measurement (Kanpolat *et al*., 2001; Bendtsen *et al*., 2019; Jones *et al.*, 2019).

Despite the lack of differences between the two interventions regarding the primary outcome, some technical difficulties ought to be pointed out: while BC demands use of a Fogarty catheter and general anesthesia, RF requires a disposable electrode, a radiofrequency generator and specialized anesthesia for a sleep-wake-

sleep procedure (because of the need to evaluate skin sensation after lesioning). Therefore, due to the need for a larger number of items and special conditions, RF is a method that may not be available in every pain center. On the other hand, BC is a very simple method and requires only a Fogarty catheter.

Recently, Gamma-knife surgery has been offered as an alternative treatment for TN. Despite the lack of invasiveness, the equipment is not widely available and the procedure lacks good results in pain-control when compared to other procedures (Lopez neurosurgery 2004; Regis j neurosurgery 2016; Wang j neurosurgery 2018). Moreover, after treatment, it may take up some time to mitigate pain (Nurmikko and Eldridge).

After thoroughly obtaining our patients' histories and physical examinations, they underwent head CT scans to assess secondary causes of TN, since our setting is one of limited resources and MVD was not the gold-standard method for treating TN at that time. As stated in the literature (Antonini *et al*., 2014), neurovascular compression (NVC) can be detected in 76% of symptomatic cases. The current classification of TN clearly states the need for MRI (in order to evaluated neurovascular conflict) (Cruccu *et al*., 2016; Headache Classification Committee, 2018), this only impacts the decision to which procedure to recommend (for instance, two patients may have the same clinical features and different MRI results: presence and absence of the vascular loop with morphological and signal changes). However, both of them could benefit from percutaneous procedures.

In our series, not all individuals were submitted to MRI scans, the high prevalence of NVC meant that we most likely included cases of classic and idiopathic TN, while excluding secondary TN, since all individuals had a normal

head CT scan. Therefore, inclusion of possible cases of CTN should not be considered to be a limitation. However, this raises the question of whether there is a role for CT scans in classifying TN: an issue that may be better evaluated in future studies, especially in resource-limited settings. And, therefore, it seems more logical to place Classical TN under primary TN in the classification.

6.1 Limitations

The sample was relatively small, given that we estimated a sample size based on the size of previous trials on TN. In a Cochrane metanalysis in 2011 (Zakrzewska and Akram, 2011), it was stated that the greatest issue with all studies was the lack of standardized clinical outcome. Therefore, direct calculation of the study power like in the present study was challenging. Based on the analysis of the papers described in this metanalysis, we estimated that 25 patients per group would be adequate. Nonetheless, we decided to add another 5 patients in each group. Some difficulties during recruitment were experienced, which led us to halt the recruitment once we had at least 15 patients in both groups and to perform the preplanned interim analysis.

The results from the present study could be used to calculate a more precise power for future studies. The sample size obtained was more appropriate and this revealed that a proper randomized clinical trial (RCT) may be unfeasible due to the large number of individuals harboring this rare condition that would be needed.

With regard to possible blinding bias, despite our attempts to blind subjects for the randomized intervention, the assessment using a pain questionnaire during the procedure revealed that the individuals who underwent RF are likely to be able to

identify their allocation group, which may have been detrimental to the study. Even though the blinding assessment revealed that the pain level during the procedure was higher in the RF group, the blinding was probably preserved since the remaining assessments did not show any differences between the groups.

Regarding the short follow-up period of 6 months, this was used in order to avoid losing patient follow-up for any reason and also to evaluate the effects of interventions over short and medium terms. Nonetheless, a 6-month period is a long time to sustain a clinical trial without any losses. On the other hand, given our lack of concrete information on the time that might be required for relapse to occur, setting the follow-up as a six-month period was arbitrary.

Despite the exploratory nature of the data reported here as secondary objectives of this study, their use may provide guidance on how to better evaluate this complex painful disorder, for future researches.

7 CONCLUSION

a) Regarding the primary objective, radiofrequency was not superior to balloon compression in controlling trigeminal pain in six months from surgery.

b) Regarding secondary objectives:

- continuous pain was equally present in both groups after follow-up.

- mood and quality of life improved significantly in both groups however no difference between them was present at follow-up.

- recurrence and frequency of pain after RF and BC was low and did not differ between groups at follow-up, despite patients receiving RF presenting more paresthetic symptoms the following month after the intervention,

ClinicalTrials.gov ID:	NCT02427074
Unique Protocol ID:	1180/09
Brief Title:	Comparison Between Radiofrequency and Balloon Compression in the Treatment of Idiopathic Trigeminal Neuralgia
Overall Status:	Terminated
Primary Completion Date:	March 31, 2019 [Actual]
Verification Date:	February 2020

The record has been Released to ClinicalTrials.gov PRS for review.

Protocol registration Records are made available to the public through the ClinicalTrials.gov web site within 2 to 5 days of release, following system validation and PRS Review. **Records that contain Results may take up to 30 days**, if the study appears to be an applicable clinical trial under 42 CFR Part 11 or an NIH-funded study. Other types of study records with results will take longer for review.

PROTOCOLO DE PESQUISA Nº: 1180/09	**Data da sessão: 21/02/2018**

TÍTULO DA PESQUISA: Estudo comparativo entre radiofreqüência tradicional, neurotomia percutânea com balão, radiofreqüência pulsátil e bloqueio anestésico do gânglio de Gasser no tratamento da neuralgia idiopática do trigêmeo em pacientes virgens de tratamento cirúrgico

PESQUISADOR(A) RESPONSÁVEL: Manoel Jacobsen Teixeira

DEPARTAMENTO: NEUROLOGIA

CONSIDERAÇÕES DO RELATOR:

Conforme solicitado no parecer anterior, os pesquisadores enviaram os subprojetos para avaliação. De fato, não houve alteração no risco, pois serão aplicados questionários aos participantes da pesquisa para avaliação do controle da dor (um braço do projeto inicial) e sensibilidade especial e geral da face (outro braço do projeto inicial). Em princípio, não fere a ética. Entretanto, seria adequado que a introdução dos projetos fosse direcionada para o objetivo de cada um, posto que os dois projetos somente diferem no título e objetivos primários, além de uma referência que foi acrescentada no segundo braço. O restante, inclusive os métodos, é idêntico. Provavelmente os questionários contenham informações que permitam as duas análises, mas a introdução deveria ser direcionada para o objetivo primário, o que recomendaria corrigir.

CONCLUSÃO: Aprovado com recomendação

ENVIAR À CONEP:	**SIM ( )** **INFORME A ÁREA TEMÁTICA:**	**NÃO (x)**

3.DURAÇÃO DA PESQUISA : 36 (trinta) meses

1 – Desenho do estudo e objetivo(s)

Essas informações estão sendo fornecidas para sua participação voluntária neste estudo, que visa comparar o uso de quatro métodos (radiofreqüência tradicional e pulsátil, compressão por balão e bloqueio anestésico) para tratar a dor causada pela neuralgia do trigêmeo. A comparação será feita em relação a efeito no alívio da dor (utilizando questionários e testes de sensibilidade na face), alterações na mastigação (questionários específicos) e na função de formação de saliva e sensibilidade ao cheiro e gosto (testes específicos)

2 – Descrição dos procedimentos que serão realizados, com seus propósitos e identificação dos que forem experimentais e não rotineiros;

O senhor(a) será submetido(a) à sedação ou anestesia local com ou sem bloqueio do gânglio, seguida de anestesia da pele no local da punção da face. Será colocada uma agulha que chegará até o nervo trigêmio do lado da dor na face. Será realizado, mediante sorteio, um dos seguintes tratamentos: radiofrequência tradicional, radiofreqüência pulsátil, compressão do nervo com a insuflação do balão ou bloqueio anestésico. A aplicação da radiofrequencia é um método onde o objetivo é causar alívio da dor, sem causar lesão extensa do nervo.

Serão feitas 6 (seis) avaliações no total: uma antes da cirurgia e cinco após a cirurgia a fim de avaliar se há melhora da dor e se há complicação do procedimento (diminuição da sensibilidade e alteração da mastigação).

3 – Relação dos procedimentos rotineiros e como são realizados – coleta de sangue por punção periférica da veia do antebraço; exames radiológicos;

Será realizada coleta de sangue para avaliação (hemograma completo, plaquetas, coagulograma e para pesquisa) e também durante procedimento será feita radioscopia para localizar balão/eletródio.

4 – Descrição dos desconfortos e riscos esperados nos procedimentos dos itens 2 e 3;

Apesar de ser um procedimento rápido algumas complicações podem ocorrer: sangramento no local e dentro do crânio, dor no local da punção, anestesia de parte da face, diminuição da força da mastigação e insucesso do procedimento (persistência da dor). No caso do bloqueio anestésico do gânglio exclusivo, se houver retorno da dor, o senhor(a) será recolocado em outro grupo, no caso de radiofreqüência pulsátil.

5 – Benefícios para o participante

Melhora da dor;

Comparar dois métodos consagrados no que tange o alívio da dor e alterações de sensibilidade e mastigação após

6 – Relação de procedimentos alternativos que possam ser vantajosos, pelos quais o paciente pode optar;

Outro tratamento cirúrgico consiste da abertura do crânio e do isolamento do nervo dos vasos que o comprimem.

7 – Garantia de acesso: em qualquer etapa do estudo, você terá acesso aos profissionais responsáveis pela pesquisa para esclarecimento de eventuais dúvidas. Os principais investigadores são os Dr. Daniel Ciampi e o pesquisador executante Dr. Hugo Sterman Neto e Dra. Cristiane Yoko Fukuda. que podem ser encontrado no endereço av. Dr. Enéas de Carvalho Aguiar, 255.Telefone(s) 3069-6329/6275. Se você tiver alguma consideração ou dúvida sobre a ética da pesquisa, entre em contato com o Comitê de Ética em Pesquisa (CEP) – Rua Ovídio Pires de Campos, 225 – 5º andar – tel: 3069-6442 ramais 16, 17, 18 ou 20, FAX: 3069-6442 ramal 26 – E-mail: cappesq@hcnet.usp.br

8 – É garantida a liberdade da retirada de consentimento a qualquer momento e deixar de participar do estudo, sem qualquer prejuízo à continuidade de seu tratamento na Instituição;

09 – Direito de confidencialidade – As informações obtidas serão analisadas em conjunto com outros pacientes, não sendo divulgado a identificação de nenhum paciente;

10 – Direito de ser mantido atualizado sobre os resultados parciais das pesquisas, quando em estudos abertos, ou de resultados que sejam do conhecimento dos pesquisadores;

11 – Despesas e compensações: não há despesas pessoais para o participante em qualquer fase do estudo, incluindo exames e consultas. Também não há compensação financeira relacionada à sua participação.

12 - Compromisso do pesquisador de utilizar os dados e o material coletado somente para esta pesquisa.
Acredito ter sido suficientemente informado a respeito das informações que li ou que foram lidas para mim, descrevendo o estudo " **ESTUDO COMPARATIVO ENTRE RADIOFREQÜÊNCIA TRADICIONAL, NEUROTOMIA PERCUTANEA COM BALAO, RADIOFREQUENCIA PULSATIL E BLOQUEIO ANESTESICO DO GÂNGLIO DE GASSER NO TRATAMENTO DA NEURALGIA IDIOPÁTICA DO TRIGÊMEO**"

Eu discuti com o Dr. Hugo Sterman Neto sobre a minha decisão em participar nesse estudo. Ficaram claros para mim quais são os propósitos do estudo, os procedimentos a serem realizados, seus desconfortos e riscos, as garantias de confidencialidade e de esclarecimentos permanentes. Ficou claro também que minha participação é isenta de despesas e que tenho garantia do acesso a tratamento hospitalar quando necessário. Concordo voluntariamente em participar deste estudo e poderei retirar o meu consentimento a qualquer momento, antes ou durante o mesmo, sem penalidades ou prejuízo ou perda de qualquer benefício que eu possa ter adquirido, ou no meu atendimento neste Serviço.

Research Paper

PAIN

Balloon compression vs radiofrequency for primary trigeminal neuralgia: a randomized, controlled trial

Hugo Sterman Neto[a,b], Cristiane Yoko Fukuda[c], Kleber Paiva Duarte[d], Valquíria Aparecida da Silva[e], Antonia Lilian de Lima Rodrigues[a], Ricardo Galhardoni Geront[f,g], Silvia R.D.T. de Siqueira[h], José Tadeu Tesseroli de Siqueira[h], Manoel Jacobsen Teixeira[ij], Daniel Ciampi de Andrade[k,*]

Abstract

Surgical procedures are necessary in up to 50% of trigeminal neuralgia patients. Although radiofrequency (RF) is more widely used, it is associated with high intraprocedural costs and long technical learning time. Other simpler procedures such as balloon compression (BC) require a lower training period and have significant lower costs. We evaluated the effects of BC and RF in pain control in primary trigeminal neuralgia in a randomized, double-blinded, head-to-head trial. Individuals were randomly allocated in 1 of 2 groups: BC and RF. Throughout pain, psychological and quality of life measurements were performed at baseline and after surgery. The main outcome was the worst pain in the last 24 hours (0-10) at 6 months postoperatively. After the inclusion of half of the estimated sample, a preplanned interim analysis was performed when 33 patients (62.1 ± 9.4 y.) completed the study. Pain intensity (confidence interval [CI] 95% 0.6 to 3.8, and −0.6 to 2.2, for BC and RF) did not significantly differ. Complications, interference of pain in daily life (CI 95% −0.1 to 2.3 and −0.4 to 2.3, for BC and RF), neuropathic pain symptoms (CI 95% 1.7 to 3.6 and 3.0 to 5.7, for BC and RF), mood (CI 95% 4.8 to 11.5 and 5.5 to 15.1, BC and RF, respectively), medication use, and quality of life (CI 95% 80.4 to 93.1 and 83.9 to 94.2, for BC and RF) were also not different. Radiofrequency presented more paresthetic symptoms than BC at 30 days after intervention. Based on these results, the study was halted due to futility because BC was not superior to RF.

1. Introduction

Trigeminal neuralgia (TN) is characterized by shock-like paroxysmal attacks distributed in one or more trigeminal branches; it may occur spontaneously, or may be evoked by mechanical triggers.[14] Trigeminal neuralgia classification is based on the presence (secondary TN) or absence (primary TN) of a disease such as multiple sclerosis or a space occupying lesion affecting the trigeminal sensory system. Primary TN is further divided into classic (presence of neurovascular compression [NVC] with morphological changes of trigeminal nerve) or idiopathic TN (inexistence NVC exists). Classic and idiopathic TN can further be divided into purely paroxysmal or associated with concomitant nonparoxysmal pain.[35] Primary TN is initially managed with medication[4,78] because the majority of individuals will initially achieve pain control through pharmacological treatment. However, approximately half of TN patients will eventually need intervention in 10 years.[4,14,28] Surgical procedures offered to these patients include: microvascular decompression (MVD)[37] for individuals with classic TN or gamma-knife surgery (GKS)[46] as an alternative for those who cannot tolerate open cranial surgery. Radiofrequency thermocoagulation (RF),[69] balloon compression (BC),[51] and glycerol rhizolysis[32] are ablative procedures that may be repeated over time and are reserved for aged patients or for those who cannot tolerate or do not desire MVD/GKS.[51] Microvascular decompression has the highest risk of major postoperative complications (stroke, meningitis, cerebral spinal fluid leak, hemorrhage in 2%, and death in 0.4%),[80] despite providing long-term pain relief in up to 70% of patients and causing no major sensory deficits postoperatively.[58,77] Gamma-knife surgery has been offered as an alternative with fair results compared to MVD in low-quality studies: GKS may take up to 30 days to be effective,[53] it provides 75% pain relief after 3 months and then 50% in 3 years.[46,58,77] Importantly, the long-term pain beneficial effects of MVD have only been determined recently,[3,4,28] and GKS is still not widely available worldwide. For these reasons, percutaneous procedures (RF and BC) are still more commonly used worldwide,[42,52,73] due to their fair rates of good results, low cost, outpatient management, and low morbidity.[42,71,75]

PAIN 00 (2020) 1–12

http://dx.doi.org/10.1097/j.pain.0000000000002070

Since its development, RF has been widely used because of its high selectivity and capacity in controlling pain.[4,38,40] However, it demands the use of expensive material,[36] highly trained anesthesiologist,[6] and experienced surgical team,[30] and carries elevated risks of sensorial disturbance, which may lead to painful anesthesia.[11,45,70] However, BC cheaper,[16,36] demands simple general anesthesia,[5,8] and is technically simpler,[2,66] providing lower rates of significant sensorial disturbances.[15,41,74]

Despite the fact that pain control may be achieved in up to 80% of the subjects treated with BC and RF, outcome measurements were heterogeneous and not well defined in the literature, and current data are mainly derived from results from large patient series.[4,38,73] No formal clinical trials directly comparing BC to RF have been conducted to date, and recent guidelines have acknowledged the lack of data allowing to recommend one technique over the other.[4] It still remains unknown whether BC can achieve good pain relief, if it can control nonparoxysmal continuous pain, and which is its side-effect profile in TN compared to more traditional RF.[4]

In this study, we conducted an original head-to-head randomized trial to assess the superiority and long-term effects of BC over RF on the different pain types of primary TN and their respective profiles of side effects.

2. Methods

This study was conducted at the pain center outpatient clinic of Hospital das Clinicas, University of São Paulo, Brazil. Patients with the diagnosis of primary TN were referred from regional neurology and pain clinics in the State of Sao Paulo. Written consent was obtained from all participants. The study was approved by our internal review board (CAPPesq 1180/09) and was registered in ClinicalTrials.gov (NCT 02427074). Enrollment occurred between May 2015 and December 2018.

2.1. Patients

Participants in the study had the following characteristics: aged 18 years or older; primary TN (according to the current criteria)[35]; no major signs of trigeminal neuropathy on examination; being refractory to medical treatment (no pain control or uncontrolled side effects with the maximum tolerated dosage of conventional medication—carbamazepine, phenytoin, oxcarbazepine, or baclofen—during the preceding year)[78]; involvement of the second or third trigeminal division; and no history of previous surgical procedure for TN. Subjects with involvement of the first trigeminal division or trigeminal neuropathy, or who refused to participate, or had difficulty in understanding the study were excluded. Brain imaging was performed on all patients to rule out secondary causes of neuralgia and make differential diagnoses. All subjects underwent a computed tomography scan of the head to rule out structural (or secondary) causes of TN. Magnetic resonance imaging (MRI) was performed in patients with suspected demyelinating diseases.

2.2. Study design

This was a prospective double-blind (subjects and raters) head-to-head randomized (superiority), clinical trial comparing the analgesic effects of BC over RF on the trigeminal ganglion for treating primary TN. The CONSORT (Consolidated Standards of Reporting Trials) recommendations were followed.[63] The patients were randomly allocated to either BC or RF in 1:1 ratio. Electronic software program (available at www.randomizer.org) was used to perform the randomization (blocks of 4). Allocation concealment was ensured by having the neurosurgeon responsible for the procedure informed of the randomization through sealed envelopes, which were handed over by a second investigator and opened as the patient entered the operating room. The surgeon responsible for all the procedures had no other role in the study. Evaluations were performed at the baseline (V0) and at 5 different postsurgical visits: 7 days, 30 days, 60 days, 90 days, and 180 days (referred to as V1, V2, V3, V4, and V5, respectively). The primary outcome of the study was the subjects' assessment of their worst pain level over the last 24 hours, at the 180-day evaluation, measured on an 11-point numerical rating scale anchored at 0 (no pain) and 10 (maximum pain imaginable) (**Fig. 1**). All the data were collected using dedicated Microsoft Excel files, stored in a cloud service, password-protected, accessible only for one investigator who was not involved in accessing or treating patients. AQ:3 [F1]

2.2.1. Blinding

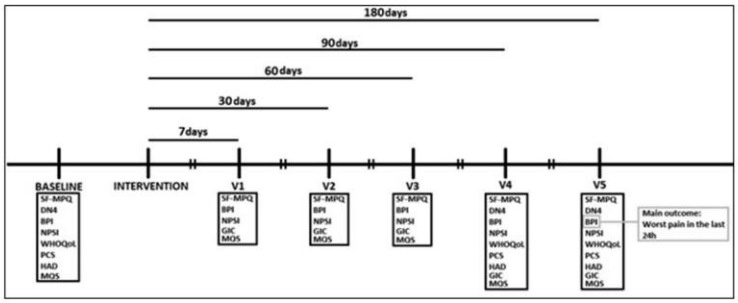
To ensure the blinding of the subjects, patients were informed that they would undergo 1 of 2 traditional percutaneous techniques for treating the symptoms of TN. The investigator responsible for the randomization and data collection never participated in the surgical procedure or in the postoperative appointments. Also, this researcher had no access to the patients' intraoperative or outpatient visit records.

A standardized questionnaire was used to assess the blinding of the study, which was filled out at the end of the trial. It was composed of 4 questions: (1) How much pain have you experienced during the surgical procedure, on a numerical rating scale from 0 (no pain) to 10 (worst pain)?; (2) Would you be able to tell which treatment you were receiving (yes/no)?; (3) If so, which group do you think you were in (group 1/group 2)?; (4) Would you be willing to undergo the procedure again if it was offered to you in the future (yes/no)?.[59]

2.3. Procedures

All the patients fasted for 6 hours before the intervention. An intravenous access was placed, and prophylactic antibiotic was given 1 hour before surgery. The anesthetic routine for the BC comprised administration of intravenous (IV) propofol (2.5 mg/kg), IV fentanyl (50-150 μg), muscle relaxant (rocuronium, 1 mg/kg), and placement of endotracheal catheter.

The subjects received atropine (0.25 mg), and sedation was maintained with sevoflurane 1 to 1.2 MAC until the end of the procedure. For RF thermocoagulation, the patients received mild sedation with propofol and fentanyl, and an O2 catheter was placed. They were then awakened for skin sensory evaluation. Under complete aseptic conditions, the skin over the needle entry-point was infiltrated with 1% lidocaine. The patient was placed in the supine position with the head perpendicular to the horizontal plane. The entry point was set as 2.5 to 3 cm laterally to the labial commissure, depending on whether the target was the third (V3) or second (V2) trigeminal division, respectively. The planes used to access the *foramen ovale* had previously been described[34,51,72]: one that passes through the ipsilateral pupil and another one 3 cm anteriorly to the tragus, also ipsilaterally. Using radioscopic imaging (Siemens, Siremobile, Erlangen, Germany), the puncturing of the foramen ovale was confirmed (using the clival line as the reference for V2; and 5 mm anteriorly to the clival line for V3).



AQ:6 **Figure 1.** Scheme depicting the follow-up and scheduled evaluations. Description: BPI, Brief Pain Inventory; DN4, Douleur Neuropathique 4; GIC, Global Impression of Change; HADS, Hospital Anxiety and Depression scale; MQS, Medication Quantification Scale; NPSI, Neuropathic Pain Symptom Inventory; PCS, Pain Catastrophizing Scale; SF-MPQ, Short-Form McGill Pain Questionnaire; WHOQoL, World Health Organization quality-of-life questionnaire.

For the BC technique, after puncturing the *foramen ovale* with a 14 G needle (BR R Becton Dickinson, Juiz de Fora, MG, Brazil), 1% lidocaine was administered to the trigeminal ganglion until facial anesthesia was attained. Then, a 4F Fogarty catheter (American Edwards Laboratory) was placed in the trigeminal cistern and insufflated with 0.7 mL of the contrast agent Iopamiron (125R, Schering, São Paulo, Brazil) until the balloon assumed a "pear shape" (**Fig. 2**) on the C-arm (approximate plateau pressure 1100 mm Hg ± 120 mm Hg).[44] Compression of the trigeminal ganglion was maintained for 120 seconds. At the end, the balloon was deflated, and the catheter and needle were removed. Mechanical compression was applied to the point of entry. For the RF technique, after puncturing the *foramen ovale* with the needle, an electrode (Radionics, 15 cm, insulated) was inserted and connected to a Radionics R generator (RFG-3C Plus). After evaluating the impedance (250-300 Ω), the trigeminal division of interest was confirmed through stimulation (sensory stimulation at 50 Hz and 0.1-0.5 V, with the patient awake to describe the area of paresthesia, and motor stimulation at a frequency of 2 Hz and 0.1-0.5 V, with the patient asleep, until masticatory movements were observed). After confirming which trigeminal division was to be targeted, we proceeded with making the lesion. This was done at 70°C lesion for 60 seconds, until static mechanical analgesia of the skin had been achieved (the pinprick sensation was tested using a safety pin and the 2 sides were compared). This process was repeated until skin anesthesia over the targeted area had been achieved.

[F2]

2.4. Pain and assessment of related factors

Subjects were evaluated using specific questionnaires, as recommended by the Initiative on Methods, Measurement, and Pain Assessment in Clinical Trials (IMMPACT).[23,24,76]

2.4.1. Brief pain inventory

It is a questionnaire that includes a pain severity index (mean of questions 3-6, with a numerical rating scale that ranged from 0 to 10, such that the lower the score was, the lower the pain level was) and measurement of the interference of pain with daily activities (mean of the 7 items, with an intensity numerical rating scale ranging from 0 to 10, where zero meant no interference and 10 for maximal interference imaginable).[27] In addition, this questionnaire provided information on pain medications and dosing. The study's primary outcome was the worst pain level over the last 24 hours, ranging from 0 to 10 on numerical rating scale.

2.4.2. McGill pain questionnaire—short form

It has descriptors[14] of pain within 3 aspects and qualities of pain: sensory–discriminative, affective–emotional, and cognitive–evaluative.[26]

2.4.3. Douleur neuropathique 4 questionnaire

This is a 10-item questionnaire used to screen for neuropathic pain. It is positive when scores 4.[62]

2.4.4. Neuropathic pain symptom inventory

It is composed of 10 items that are presented as numerical rating scales with a range from 0 to 10, each referring to a specific feature: superficial spontaneous pain (question 1), deep spontaneous pain (mean of questions 2 and 3), paroxysmal pain (mean of question 5 and 6), evoked pain (mean of questions 8, 9, and 10) and paresthesia/dysesthesia (mean of questions 11 and 12).[19] The total score possible is 100. The temporal aspects of continuous and paroxysmal pain are assessed in question 4 (duration of spontaneous pain over the last 24 hours) and question 7 (number of pain attacks over the last 24 hours). Neuropathic pain symptom inventory was also used here to evaluate nonparoxysmal pain: scores of 4 or higher than the mean in the first domain (superficial spontaneous pain) and second domain (deep spontaneous pain) were considered to represent continuous pain.

2.4.5. Pain catastrophizing scale

It consists of a 13-item scale, on which each item can be scored from 0 to 4 each, thus giving a total score of 0 to 52.[64] The higher the score is, the more elevated the distress is.

2.4.6. Hospital anxiety and depression scale

It is a 14-item questionnaire (7 items for anxiety and 7 for depression symptoms, with scores ranging from 0 to 3 each) that

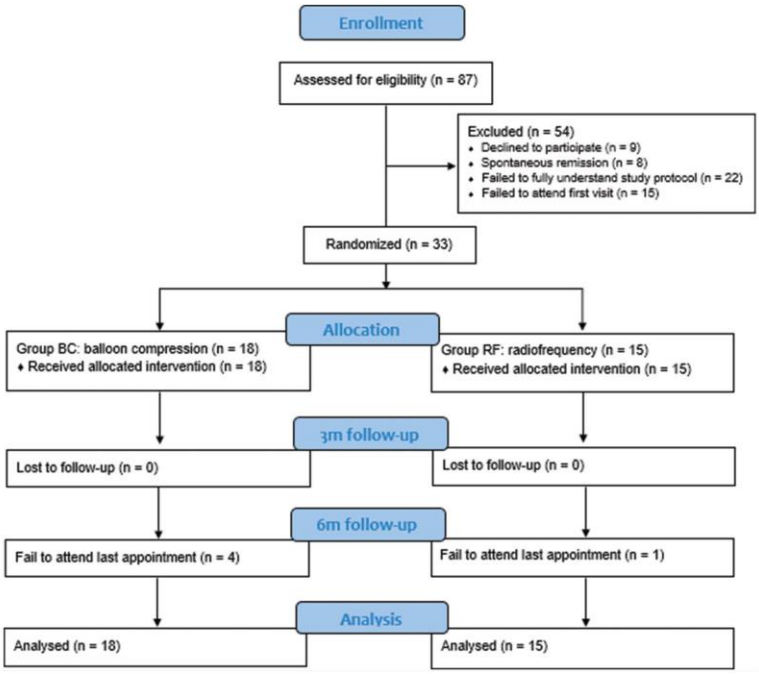


Figure 2. CONSORT flowchart of the study.

aids in screening for mood disorders, with total scores from 0 to 21 for anxiety and for depression.[54] Higher scores suggest depression/anxiety.

2.4.7. World Health Organization quality-of-life questionnaire—brief form

This is a short 26-item version of a standardized 100-item questionnaire that evaluates 4 domains of quality of life: physical, psychological, social relationships, and environmental relationships.[29] The higher the scores are, the better the quality of life is.

2.4.8. Global impression of change

This is a scale used by the patient global impression of change (p-GIC) and evaluator (c-GIC) to rate the global evolution of their pain since the first visit.[19,24] In both cases, the GIC included 7 ranks ranging from 1 to 7 (1 = very much improved, 2 = moderately improved, 3 = slightly improved, 4 = no change; 5 = slightly worsened; 6 = moderately worsened; 7 = very much worsened).

2.4.9. Medication quantification scale version 3

It is for quantifying the medications used by the patient and their dosages. It provides a weighted final score for the "medication burden."[33]

2.5. Statistical analysis

The variables were expressed using absolute values and frequencies (for categorical variables), and mean values and SDs along with minimum and maximum values for continuous variables. Data were analyzed as intention to treat. The effect of the interventions on the main outcome was assessed using a series of generalized estimation equations (GEE). The measurements at the baseline and at 7, 30, 60, and 180 days after the intervention were evaluated longitudinally, and the fact that all measurements were estimated for the same patient was accounted for. Because the outcome presented nonnormal distribution, its raw numerical values were recategorized as indicator variables with cutoff points greater than or equal to 2, 3, 5, or 7 points. These dichotomous values were analyzed through GEE with binomial distribution. The models evaluated the association between the outcome and the 2 interventions, and differences at the baseline were accounted for. We reported the results as the predicted means for numerical outcomes and as odds ratios for categorical outcomes, along with 95% confidence intervals.[60] The Kolmogorov–Smirnov test was used to test the normal distribution of variables. For nonnormally distributed variables, comparisons between groups were made using the Mann–Whitney test and Pearson chi-square test. The Student t test was used for normally distributed variables. For patients to be included in the analyses, they needed to have attended at least

80% of the visits and to have provided at least 80% of the information at each clinical visit. Data imputation was done by using the last-observation-carried-forward methodology. Because there was a paucity of formal clinical trials on ablative surgery for NT,[79] no formal sample size calculation could be performed beforehand. Therefore, we designed a pragmatic clinical trial: we used a convenience sample of NT patients based on the sample size of previous studies (n = 30 per arm),[25,79] to assess equivalence between arms. Variables at baseline were tested for differences because the trial presents a restricted number of participants. A preplanned interim analysis, approved by the institutional review board (IRB), was envisaged when half of the total sample was reached in both groups, to access safety and pain control data and to assess whether there was any need to revise the number of subjects needed. The interim results were analyzed by an external research panel and one of the following decisions would be made: (1) to stop the trial because significant differences between the arms had already been discerned; (2) to stop the trial due to futility; or (3) to pursue the trial with a larger sample size calculated based on the information obtained from the first part of the study. The statistical analyses were performed using IBM SPSS (Statistical Package for the Social Sciences) v17.0 and R-Project.[56] The sample size for the difference in slopes between the BC and the conventional RF groups was calculated based on previous published data,[25,79] to yield a power of 0.8 and detect a difference in slopes of 1.5, with a residual variance of 1 and a significance level of 0.05.[22] Individual patient's data will be available upon request. Reports regarding statistical analysis and study protocol can be obtained upon request to the corresponding author.

3. Results

3.1. Descriptive data and baseline assessment

Eighty-seven patients were assessed for eligibility. Thirty-three (25 females; 62.18 ± 9.4 years old) were included (see [F3] CONSORT flow-chart—**Fig. 3**) for the interim analysis: 57.6% had the mandibular division affected and 21 had right-sided TN. [T1] **Table 1** shows the subjects' characteristics and demographics, along with comparisons between the groups. The following results represent the outcomes from the preplanned interim analyses. Both groups showed similar medication usage at the baseline, as depicted by the MQS score (10.63 ± 6.21 for BC; 12.47 ± 4.44 for RF; $P = 0.292$). Main baseline variables were [T2] similar between groups (**Table 2**).

3.2. Results regarding pain and related factors

3.2.1. Main outcome

The main outcome of the study was not significantly different [T3] between groups ($P = 0.78$). **Table 3A** displays information on the study's main outcome, analyzed by GEE, which was categorized as higher or lower than 5. A similar pattern was observed when recategorizing the worst pain level over the last 24 hours into higher or lower than 2, 3, or 7, as depicted in **Table 3B**, although an expected reduction in pain intensity overtime in each group [F4] could be noted (**Fig. 4**).

3.2.2. Secondary outcomes

At 180 days after the intervention, the patients in the BC group reported higher levels of pain (Brief pain inventory—pain intensity index), compared with those in the RF group, although not clinically or statistically significant difference was observed (confidence interval 95% 0.17 to 2.58 and −0.63 to 1.93, BC and RF, respectively). The DN4 questionnaire was positive in 33.3% and 60% of the individuals, respectively, in the BC and RF groups at 6 months. These proportions were lower than at baseline (88.9% and 80% for BC and RF, respectively), but no difference was observed between the groups ($P = 0.126$). No significant difference was found on MPQ scores (12.89 ± 1.71 and 12.20 ± 2.51; 3.39 ± 4.23 and 2.20 ± 3.86; for BC and RF at the baseline and last appointment, respectively; $P = 0.292$ and $P = 0.94$). Concerning the pain phenotype, patients in the RF group reported more paresthetic symptoms than did those in the BC group (2.08 ± 1.99 vs 3.97 ± 1.96, respectively; $P = 0.017$). Moreover, there was a higher number of RF patients who were completely pain-free (100% of these individuals), compared with the BC group (4.55 ± 0.78 vs 5.00 ± 0.00; $P = 0.015$) at the first postoperative assessment (visit 1 at 7 days postoperatively), assessed by the specific item on number of pain attacks from the NPSI questionnaire. The paresthesia symptom scores were significantly higher in the RF group at 30 days (V2; $P = 0.01$), but these symptoms were resolved during the follow-up (V5; $P = 0.294$). At 90 days (V4), the individuals in the BC group presented lower NPSI total scores (9.61 ± 15.2 vs 15.07 ± 20.75 in the RF group; $P = 0.038$), but at the last evaluation, this difference was no longer present ($P = 0.598$). Global impression of change, despite presenting with no difference at the last appointment ($P = 1.0$), demonstrated elevated proportions of highly satisfied individuals in both groups (88.9% for BC and 86.7% for RF).

Patients with main paroxysmal pain but presenting concomitant continuous pain at baseline comprised 66.7% of the BC group and 53.3% of the RF group. At the last assessment, these proportions were 5.6% and 20%, respectively ($P = 0.308$). Patients with purely paroxysmal pain at the baseline were 16.7% in the BC group and 40% in the RF group ($P = 0.239$). After the follow-up, these proportions were 72.2% and 66.7% ($P = 0.730$). Other mood, quality of life, and medication used variables were not significantly different between groups and are presented in supplementary file (available at http://links.lww.com/PAIN/B174). Concomitant nonparoxysmal pain was present in 28% and 26%, harboring TN in maxillary and mandibular division, respectively. At 6 months, this proportion was 57% and 79%, respectively.

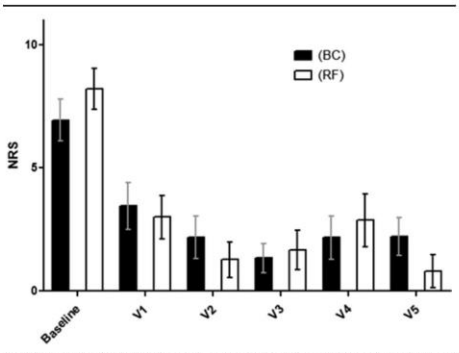

Figure 3. Numerical rating scale of main outcome (worst pain level over the last 24 hours). Description: Results expressed as mean and standard error between groups, over time. BC, balloon compression; RF, radiofrequency.

Table 1

Demographics and baseline pain characteristics of all patients and subgroups, and comparisons between the variables.

Characteristics	Total (33)	Group 1 (BC) (n = 18)	Group 2 (RF) (n = 15)	P
Age (in y)	62.18 ± 9.4 (40-78)	65 ± 9.42 (45-78)	58.8 ± 8.47 (40-71)	0.058

L	12 (36.4%)	4 (22.2%)	8 (53.3%)	
Presence of other previous nontrigeminal chronic pain	18 (54.5%)	12 (66.7%)	6 (40%)	0.126

The values are presented as mean + SD (range). Significance set at $P < 0.05$.
BC, balloon compression; RF, radiofrequency; V2, maxillary division; V3, mandibular division; R, right; L, left.

3.3. Procedures

All the patients were discharged from hospital within 24 hours after the intervention. There was no difference in postoperative pain between the groups: patients in both groups experienced new pain after the procedure, easily controlled with common painkillers (the intensity and duration were similar). Radiofrequency patients required an average of 2 to 3 lesion cycles to achieve hypoalgesia in the trigeminal territory of interest.

3.4. Blinding assessment

Pain during the procedure was evaluated because this is a possible source of blinding bias. The mean values (ranging from 0 to 10) and SDs for BC and RF were, respectively, 1.33 ± 2.06 and 4 ± 2.27 ($P = 0.02$). After completion of the protocol, 44.4% of the individuals in group BC reported that they were able to tell which group they had been allocated to, and 66.7% of these individuals guessed it right. In group RF, the proportion was 37.5% for both questions ($P = 0.35$). When asked if they would be willing to undergo the procedure again if it was offered, the proportions were 55.5% and 50%, for groups BC and RF, respectively. None of these proportions were statistically significant ($P = 1.0$).

3.5. Effect and sample size

The preplanned interim analysis was performed at the time when each arm reached half of the scheduled number of subjects, to evaluate the safety and effect size of the protocol. The power of the study was 4.7%. An update of the sample size was made based on the results from this trial, to estimate the sample size necessary to detect a difference between groups in a subsequent trial using generalized estimated equations (power of 80% and a significance level of 0.05). The number necessary per arm was 1457, thus rendering uncertain the clinical value of the difference between BC and RF for TN. Therefore, the study was halted due to futility after a meeting between researchers and an external scientific board.

4. Discussion

We report the results from the first attempt to prospectively prove superiority of BC over RF for primary TN. No significant differences were found between BC and RF for the primary outcome. The decision regarding which treatment to offer patients with TN has been an issue of great debate for a long time. Although adequate pain control has been achieved through use of carbamazepine,[13] a significant proportion of patients will suffer from untenable side effects or may not reach satisfactory pain-attack control.[4,14,28] Percutaneous procedures have been used for over 4 decades without clear evidence regarding which of these is most effective for controlling TN pain or differences in safety. The literature has an abundancy of large series of patients who underwent ablative interventions, but the outcomes have often been measured using different and heterogeneous pain outcome measures, which hampers generalization. Moreover, the characteristics of the pain in TN are often not considered in depth: for instance, number of pain attacks, intensity of pain attacks, reduction of medication burden, and the presence of nonparoxysmal pain were rarely assessed systematically.[31]

Considering procedure-related risks and technical difficulties, it seems that ablative procedures are preferred over MVD for a number of reasons[4,31]: simplicity, outpatient management, and low profile of severe side effects. In addition, the outcomes of the latter have been suggested to be superior in high-volume

centers.[39] Historically, individuals often underwent percutaneous ablative procedures for the abovementioned reasons and because of the need for a learning curve for MVD.[9,38,42,67,71,80] Since the time when ablative procedures became part of the armamentarium of treatment options for TN,[51,69] the procedures most used have been BC and RF. Despite their apparent safety, a

Table 3

Predicted odds ratio for the worst pain level over the last 24 hours.

	Group 1 (BC) (n = 18)	Group 2 (RF) (n = 15)	*P*
a)			
Worst pain in the last 24 h above 5a	1.12 (0.51, 2.49)	1 [referent]	0.78
b)			
Worst pain in the last 24 h above 2b	1.07 (0.48, 2.39)	1 [referent]	0.86
Worst pain in the last 24 h above 3b	1.06 (0.48, 2.33)	1 [referent]	0.88
Worst pain in the last 24 h above 7b	1.22 (0.51, 2.93)	1 [referent]	0.66

Comparison of the "worst pain level over the last 24 h" transformed to a dichotomous variable (a: above 5; b: above 2, above 3, and above 7). The values are presented as odds ratio (95% confidence intervals). Significance is set as $P < 0.05$.
BC, balloon compression; RF, radiofrequency.

deeper and standardized evaluation of their pain-relief effect is still lacking in the literature. The outcome most frequently used in most reports was the rate of recurrence, although patients under remission of paroxysmal pain often experience other types of pain (ie, nonparoxysmal)[41,73] and side effects of surgery (skin numbness and masticatory abnormalities).[11,15,20,21,43,49,50,55,68] Despite the lack of differences between the 2 interventions regarding the primary outcome in this study, some technical issues ought to be pointed out: although BC demands use of a Fogarty catheter and general anesthesia, RF requires a disposable electrode, an RF generator, and specialized anesthesia for a sleep–wake–sleep procedure (because of the need to evaluate skin sensation after lesioning). Although a larger number of items are needed, the fact that skin sensation was tested after each cycle of RF likely protected excessive deafferentation and possible subsequent long-term painful anesthesia. Therefore, because of the need for a larger number of items and special conditions, RF is a method that may not be readily available in every pain center. However, since BC is a simple method that demands fewer items, associated to the fact that it offers clinically similar pain-control capacity, restricted-resource centers with lower expertise in RF should consider BC for treating TN.

The sample size used in this study was based on previous reports of the effect size in surgical TN trials.[79] A *post hoc* power analysis calculated based on this study's results suggested that if a real difference in pain relief should exist between the 2 interventions, a clinical trial would require a significant number of participants in each arm, larger than the sum of all the patients enrolled in all TN trials performed to date.[9,42,66,70,71] For example, the largest series published enrolled 1600 patients over 25 years,[40] which strongly suggests that the clinical difference between both techniques are likely to be irrelevant.

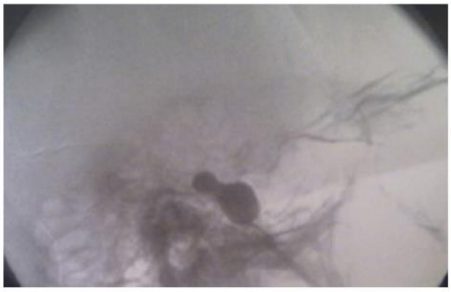

Figure 4. Balloon compression imaging. Description: Fluoroscopic image of the "pear-shape" of the Fogarty catheter during balloon compression of the trigeminal nerve.

The current IASP/IHS subclassification of TN is based on MRI assessment of the posterior fossa and detection of NVC.[35] Here, only 18% of the individuals had MRI. The remaining had secondary causes excluded with computerized tomography. It is known that 25% of individuals with typical TN may not have detectable NCV on MRI on the side of their pain.[1] This means that our sample probably included a largest proportion of patients with NVC, and would probably be classified with classic TN, should MRI assessment be performed systematically. Importantly, although MRI studies are mandatory when NVC is envisaged, its importance for patients undergoing ablative procedures remains to be determined. In latest recommendations, this point is further highlighted, and it is further acknowledged that although MRI is fundamental for the determination of microvascular compression of the trigeminal nerve (to classify primary TN as classic, subsequently enabling MVD as a surgical treatment possibility), it is not required for the diagnosis of TN per se.[4]

The peculiar main paroxysmal nature of TN imposes some challenges in quantifying pain because paroxysmal pain may not be well suitable for assessment by regular "general" pain intensity-based visual analogue scale or numeric ranking scale approaches. Nonparoxysmal concomitant pain in TN has been a recognized feature of the TN syndrome.[18] Indeed, TN was classified into 2 groups, according to the frequency of continuous nonparoxysmal pain: TN1 or typical TN when paroxysms are predominant, and TN2 or atypical TN when concomitant continuous pain occurs at least in 50% of the time.[7,10,12] In fact, TN patients frequently have secondary nonparoxysmal pain, which is less frequently assessed in both pharmacological and surgical trials, but may be disabling and negatively impact quality of life.[17,47] Here, we tried to overcome this limitation by assessing both the paroxysmal and nonparoxysmal pains using NPSI, which enables specific scoring of these different pain symptoms. Indeed, we found that both BC and RF decreased levels of paroxysmal and nonparoxysmal pain, with no difference between arms. Here, we used specific NPSI scores to evaluate occurrences of continuous pain. When compared to the baseline, despite the proportion of nonparoxysmal pain decrease after surgical treatments compared to baseline, no difference was observed between groups at the last appointment. These original findings suggest that the both approaches provide similar changes in continuous pain after percutaneous procedures. Continuous pain in TN may be due to a wide range of causes and their presence may have influenced previous publications where their presence was not specifically assessed.[48,57,61,65] Here, we also found that the proportion of this nonparoxysmal pain was higher in patients treated for TN mainly located in the mandibular division of the trigeminal nerve, which may be caused by postoperative masticatory weakness.[20,21]

We also found that patients receiving RF experienced more paresthetic symptoms after the procedure (one week and 4 weeks after surgery), despite presenting fewer pain attacks at 4 weeks compared to the BC group. This confirms that this symptom may be expected as a side effect after percutaneous RF, but may most likely subside after one month. Also, patients who underwent BC presented lower total NPSI scores at 90 days which, despite not being a main outcome of this study, corroborates the common knowledge that BC leads to less skin sensory disturbances. Importantly, these group differences disappeared in the last evaluation.

Some limitations of this study should be pointed out. With regard to possible blinding bias, despite our attempts to blind subjects for the randomized intervention, the assessment using a pain questionnaire during the procedure revealed that the individuals who underwent RF are likely to be able to identify their allocation group. Although the blinding assessment revealed that the pain level during the procedure was higher in the RF group, the blinding was probably preserved because the remaining assessments did not show any differences between the groups. The six-month follow-up period is relatively short and may not comprise the whole time to relapse. However, we chose this time-frame because it allows for the classification of pain as chronic (>3 months), while maintaining the double-blind nature of the trial. Also, the sample was relatively small, given that its estimation was based on the size of previous trials on TN, and no studies addressing direct comparisons between ablative procedures for TN were available. In a Cochrane meta-analysis,[79] it was stated that the greatest issue with all interventional TN studies was the lack of standardized clinical outcomes. Therefore, direct calculation of the study power like in this study was challenging and mainly based on previously published articles.[25,79] In fact, results from this study could be used to calculate a more precise power for future studies.

In summary, our study showed that pain relief after RF and BC was globally similar, with no superiority of BC over RF for primary TN. However, as we have shown, BC leads to less dysesthesia than RF (and potentially less postprocedural neuropathic pain). And, because BC requires less use of anesthetics, has a shorter technical learning curve, and has lower costs than RF, BC could be preferentially recommended to patients undergoing ablative procedures. We also found similar effects for other components of neuropathic pain such as nonparoxysmal pain, and a relatively small number of adverse events in both groups.

Letter to Editor:

We thank Venda Nova et al.[7] for their interest in our work. We fully agree that trigeminal neuralgia (TN), despite being a rare disorder, is a syndrome that would benefit from a joint effort from healthcare providers and patients to develop and validate outcome measurements that are comprehensive, relevant, and comprehensible for end users.

However, it must also be acknowledged that sources of pain and suffering are not only diverse in patients with TN[4] but may as well stem from undue effects of surgical treatments. That means that finding a common denominator relevant to all patients under a patient-reported outcome framework would only partially solve these challenges because it would provide a validated tool to assess TN but not necessarily help detangling all the variables influencing good outcomes after each of the treatment interventions. For instance, as we have highlighted,[9] pain in TN is paroxysmal by definition, but nonparoxysmal continuous ongoing pain may be present in a significant proportion of patients and may respond differently to treatments aimed at paroxysmal pain. To that, we have potential unwanted effects of surgical interventions such as chronic postcraniotomy pain[1] and hearing loss in the case of neurovascular decompression or posttraumatic neuropathic pain (with all its possible combinations of signs and symptoms) in a deafferented skin (or mucosa) secondary to ablative procedures. One may also add musculoskeletal pain in masticatory muscles originating after ablative procedures,[3,5] which are more frequent when the mandibular subdivision of the trigeminal nerve is affected. Not to mention one frequently forgotten issue: in clinical trials, individuals with non-TN pain syndromes co-occurring with TN are frequently excluded from studies. Because chronic pain affects at least 18%[8] of the general population, real-life patients with TN may potentially harbor concomitant causes of face or head pain, such as migraine and cervicogenic headache[6] or may be under central-acting medications for extracranial chronic pain conditions that may influence TN pain outcomes or increase adverse events to TN interventions. All these above-mentioned instances may influence the perception of improvement after interventional treatments and may add noise to the assessment of specific treatment efficacy.

Given these challenges, one could argue that a complementary and pragmatic approach would be to continue using general measurements of pain intensity as end points (that do need to be validated according to patient-reported outcome guidelines), and to them, add a comprehensive set of tools to characterize secondary outcomes and potential side effects of treatment individually. For instance, we used the Neuropathic Pain Symptom Inventory (NPSI)[2] as a measure of the temporal profile of TN paroxysmal and nonparoxysmal symptoms. Indeed, the NPSI allowed us to show that radiofrequency thermocoagulation leads to more paresthetic symptoms after the procedure (up to one-month postsurgery), decreasing afterwards to levels similar to the balloon compression group. In addition, the total scores of the NPSI were lower at 90 days postprocedure in the balloon compression group compared with the radiofrequency group. Again, these differences waned in time during long-term follow-up. Thus, the field of TN, one of the most challenging pain syndromes known, urgently needs the development and validation of (primary) outcome measurements that matter to those in pain, as well as a more comprehensive and detailed assessment of the different "pains" that may occur in TN and after its treatments.

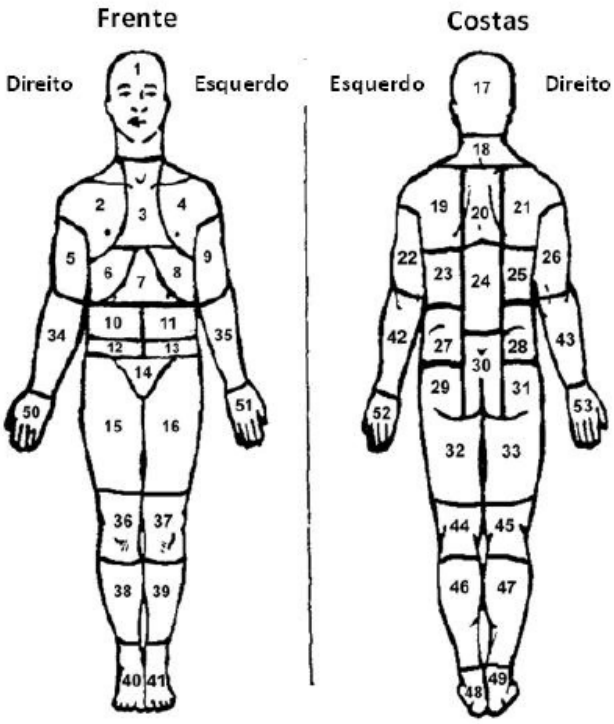
APPENDIX

Appendix A - Brief Pain Inventory

1) Durante a vida, a maioria das pessoas apresenta dor de vez em quando (dor de cabeça, dor de dente, etc.). Você teve hoje, dor diferente dessas?

1.Sim ☐ 2.Não ☐

2) Marque sobre o diagrama, com um X, as áreas onde você sente dor, e onde a dor é mais intensa.



3)Circule o número que melhor descreve a pior dor que você sentiu nas últimas 24 horas.

Sem dor O 1 2 3 4 5 6 7 8 9 10 Pior dor possível

4) Circule o número que melhor descreve a dor mais fraca que você sentiu nas últimas 24 horas.

Sem dor O 1 2 3 4 5 6 7 8 9 10 Pior dor possível

5) Circule o número que melhor descreve a média da sua dor.

Sem dor O 1 2 3 4 5 6 7 8 9 10 Pior dor possível

6) Circule o número que mostra quanta dor você está sentindo agora (neste momento).

Sem dor O 1 2 3 4 5 6 7 8 9 10 Pior dor possível

7) Quais tratamentos ou medicações você está recebendo para dor?

Nome	Dose/ Freqüência	Data de Início

8) Nas últimas 24 horas, qual a intensidade da melhora proporcionada pelos tratamentos ou medicações que você está usando?

Circule o percentual que melhor representa o alívio que você obteve.

Sem alívio | 0% 10% 20% 30% 40% 50% 60% 70% 80% 90% 100% | alívio completo

9) Circule o número que melhor descreve como, nas últimas 24 horas, a dor interferiu na sua:

Atividade geral

Não interferiu | 0 1 2 3 4 5 6 7 8 9 10 | interferiu completamente

Humor

Não interferiu | 0 1 2 3 4 5 6 7 8 9 10 | interferiu completamente

Habilidade de caminhar

Não interferiu | 0 1 2 3 4 5 6 7 8 9 10 | interferiu completamente

Trabalho

Não interferiu | 0 1 2 3 4 5 6 7 8 9 10 | interferiu completamente

Relacionamento com outras pessoas

Não interferiu | 0 1 2 3 4 5 6 7 8 9 10 | interferiu completamente

Sono

Não interferiu | 0 1 2 3 4 5 6 7 8 9 10 | interferiu completamente

Habilidade para apreciar a vida

Não interferiu | 0 1 2 3 4 5 6 7 8 9 10 | interferiu completamente

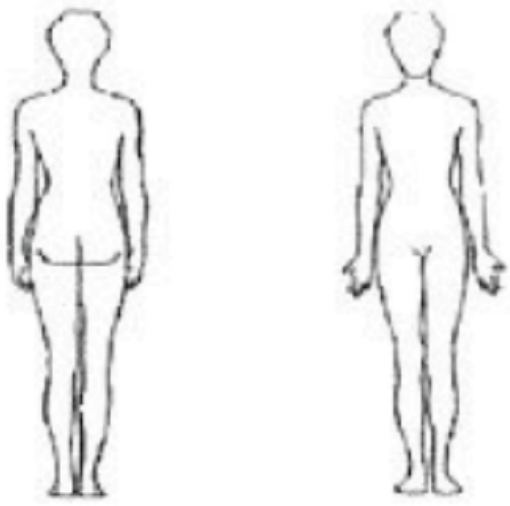
Intensidade da dor



Localização da dor (marcar a localização)

Appendix C - Douleur Neuropatique 4

Por favor, nas quatro perguntas abaixo, complete o questionário marcando uma resposta para cada número:

ENTREVISTA DO PACIENTE

Questão 1: A sua dor tem uma ou mais das seguintes características?

	Sim	Não
1- Queimação		
2- Sensação de frio dolorosa		
3- Choque elétrico		

Questão 2: Há presença de um ou mais dos seguintes sintomas na mesma área da sua dor?

	Sim	Não
4- Formigamento		
5- Alfinetada e agulhada		
6- Adormecimento		
7- Coceira		

EXAME DO PACIENTE

Questão 3: A dor está localizada numa área onde o exame físico pode revelar uma ou mais das seguintes características?

	Sim	Não
8- Hipoestesia ao toque		
9- Hipoestesia a picada de agulha		

Questão 4: Na área dolorosa a dor pode ser causada ou aumentada por:

	Sim	Não
10- Escovação		

Appendix D - Neuropathic Pain Symptom Inventory

Você tem sofrido de dor devido a lesões ou doença do sistema nervoso. Esta dor pode ser de diversos tipos. Você pode ter dor espontânea, ex: dor na ausência de qualquer estímulo, que pode ser duradoura ou ocorrer em ataques breves. Você pode também ter dor provocada ou aumentada por leve toque, pressão, ou contacto com o frio na área dolorosa. Você pode sentir um ou mais tipos de dor. Este questionário foi desenvolvido para ajudar o seu médico a melhor avaliar e tratar diferentes tipos de dor que possa sentir.

*Nós queremos saber se você sente dor espontânea, isto é dor sem qualquer estímulo. Para cada das seguintes questões, por favor seleccione o número que melhor descreve a sua **gravidade média da dor espontânea durante as últimas 24 horas**. Seleccione o número 0 se você não sentiu tal dor (circule um número apenas).*

Q1. A sua dor dá a sensação de queimadura?

Não queima	0	1	2	3	4	5	6	7	8	9	10	A pior queimadura imaginável

Q2. A sua dor dá a sensação de apertar?

Não aperta	0	1	2	3	4	5	6	7	8	9	10	Aperta o pior imaginável

Q3. A sua dor dá a sensação de pressão?

Sem pressão	0	1	2	3	4	5	6	7	8	9	10	A pior pressão imaginável

Q4. **Durante as últimas 24 horas**, a sua dor espontânea tem estado presente:
Seleccione a resposta que melhor descreve o seu caso

Permanentemente	☐
Entre 8 e 12 horas	☐
Entre 4 e 7 horas	☐
Entre 1 e 3 horas	☐
Menos que 1 hora	☐

*Nós queremos saber se você teve ataques breves de dor. Para cada das seguintes questões, por favor seleccione o número que melhor descreve a **gravidade média dos seus ataques de dor durante as últimas 24 horas**. Seleccione o número 0 se você não sentiu tal dor (circule um número apenas).*

Q5. A sua dor dá a sensação de choque eléctrico?

Sem choque eléctrico	0	1	2	3	4	5	6	7	8	9	10	O pior choque eléctrico imaginável

Q6. A sua dor dá a sensação de apunhalar?

Sem punhalada	0	1	2	3	4	5	6	7	8	9	10 A pior punhalada imaginável

Q7. **Durante as últimas 24 horas**, quantos destes ataques de dor teve?

Seleccione a resposta que melhor descreve o seu caso

Mais de 20 ☐
Entre 11 e 20 ☐
Entre 6 e 10 ☐
Entre 1 e 5 ☐
Sem ataque de dor ☐

*Nós queremos saber se você sente dor provocada ou aumentada por leve toque, pressão, contacto com frio na área onde dói. Para cada das seguintes questões, por favor seleccione o número que melhor descreve a **gravidade média da dor provocada durante as últimas 24 horas**. Seleccione o número 0 se você não sentiu tal dor (circule um número apenas).*

Q8. A sua dor é provocada ou aumentada por um leve toque na área dolorosa?

Sem dor	0	1	2	3	4	5	6	7	8	9	10 A pior dor imaginável

Q9. A sua dor é provocada ou aumentada por pressão na área dolorosa?

Sem dor	0	1	2	3	4	5	6	7	8	9	10 A pior dor imaginável

Q10. A sua dor é provocada ou aumentada por contacto com algo frio na área dolorosa?

Sem dor	0	1	2	3	4	5	6	7	8	9	10 A pior dor imaginável

*Nós queremos saber se você sente sensações anormais **na zona onde dói**. Para cada das seguintes questões, por favor seleccione o número que melhor descreve a **gravidade média das sensações anormais durante as últimas 24 horas**. Seleccione o número 0 se você não sentiu tal dor (circule um número apenas).*

Q11. Sente alfinetes e agulhas?

Sem alfinetes nem agulhas	0	1	2	3	4	5	6	7	8	9	10 Os piores alfinetes e agulhas imagináveis

Q12. Sente dormente?

Sem dormência	0	1	2	3	4	5	6	7	8	9	10 O mais dormente imaginável

Appendix E - World Health Organization Quality of Life Brief-Form

Instruções:

Este questionário é sobre como você se sente a respeito de sua qualidade de vida, saúde e outras áreas de sua vida. **Por favor responda a todas as questões**. Se você não tem certeza sobre que resposta dar em uma questão, por favor, escolha entre as alternativas a que lhe parece mais apropriada. Esta, muitas vezes, poderá ser a sua primeira escolha.

Por favor, tenha em mente seus valores, aspirações, prazeres e preocupações. Nós estamos perguntando o que você acha de sua vida, tomando como referência as **duas últimas semanas**. Por exemplo, pensando nas duas últimas semanas, uma questão poderia ser:

Você recebe dos outros o apoio que necessita?

Nada	Muito pouco	Médio	Muito	Completamente
1	2	3	4	5

Você deve circular o número que melhor corresponde ao quanto você recebe dos outros o apoio que necessitou nestas duas últimas semanas. Portanto, você deve circular o número 4 se recebeu "muito" apoio. Você deve circular o número 1 se você não recebeu "nada" de apoio.

Por favor, leia cada questão, veja o que você acha e circule no número que lhe parece a melhor resposta.

1.Como você avaliaria a sua qualidade de vida?

Muito ruim	Ruim	Nem ruim nem boa	Boa	Muito boa
1	2	3	4	5

2.Quão satisfeito você está com sua saúde?

Muito insatisfeito	Insatisfeito	Nem satisfeito nem insatisfeito	Satisfeito	Muito satisfeito
1	2	3	4	5

As questões seguintes são sobre o quanto você tem sentido algumas coisas nas últimas duas semanas.

3.Em que medida você acha que sua dor (física) impede você de fazer o que você precisa?

Nada	Muito pouco	Mais ou menos	Bastante	Extremamente
1	2	3	4	5

4.O quanto você precisa de algum tratamento médico para levar a sua vida diária?

Nada	Muito pouco	Mais ou menos	Bastante	Extremamente
1	2	3	4	5

5.O quanto você aproveita a vida?

Nada	Muito pouco	Mais ou menos	Bastante	Extremamente
1	2	3	4	5

6.Em que medida você acha que sua vida tem sentido?

Nada	Muito pouco	Mais ou menos	Bastante	Extremamente
1	2	3	4	5

7.Quanto você consegue se concentrar?

Nada	Muito pouco	Mais ou menos	Bastante	Extremamente
1	2	3	4	5

8.Quão seguro você se sente em sua vida diária?

Nada	Muito pouco	Mais ou menos	Bastante	Extremamente
1	2	3	4	5

9.Quão saudável é o seu ambiente físico?

Nada	Muito pouco	Mais ou menos	Bastante	Extremamente
1	2	3	4	5

As questões seguintes perguntam sobre quão completamente você tem sentido ou é capaz de fazer certas coisas nas últimas duas semanas.

10.Você tem energia suficiente para o seu dia-a-dia?

Nada	Muito pouco	Médio	Muito	Completamente
1	2	3	4	5

11.Você é capaz de aceitar a sua aparência física?

Nada	Muito pouco	Médio	Muito	Completamente
1	2	3	4	5

12.Você tem dinheiro suficiente para satisfazer suas necessidades?

Nada	Muito pouco	Médio	Muito	Completamente
1	2	3	4	5

13.Quão disponíveis estão para você as informações que precisa no seu dia-a-dia?

Nada	Muito pouco	Médio	Muito	Completamente
1	2	3	4	5

14.Em que medida você tem oportunidade de atividades de lazer?

Nada	Muito pouco	Médio	Muito	Completamente
1	2	3	4	5

As questões seguintes perguntam sobre quão satisfeito você se sentiu a respeito de vários aspectos de sua vida nas últimas duas semanas.

15.Quão bem você é capaz de se locomover?

Muito ruim	Ruim	Nem ruim nem bem	Bem	Muito bem
1	2	3	4	5

16.Quão satisfeita você está com seu sono?

Muito insatisfeito	Insatisfeito	Nem satisfeito nem insatisfeito	Satisfeito	Muito satisfeito
1	2	3	4	5

17.Quão satisfeita você está com a sua capacidade de desempenhar as atividades do seu dia-a-dia?

Muito insatisfeito	Insatisfeito	Nem satisfeito nem insatisfeito	Satisfeito	Muito satisfeito
1	2	3	4	5

18.Quão satisfeito você está com a sua capacidade para o trabalho?

Muito insatisfeito	Insatisfeito	Nem satisfeito nem insatisfeito	Satisfeito	Muito satisfeito
1	2	3	4	5

19.Quão satisfeito(a) você está consigo mesmo?

Muito insatisfeito	Insatisfeito	Nem satisfeito nem insatisfeito	Satisfeito	Muito satisfeito
1	2	3	4	5

20.Quão satisfeito você está com suas relações pessoais (amigos, parentes, conhecidos, colegas)?

Muito insatisfeito	Insatisfeito	Nem satisfeito nem insatisfeito	Satisfeito	Muito satisfeito
1	2	3	4	5

21.Quão satisfeito você está com a sua vida sexual

Muito insatisfeito	Insatisfeito	Nem satisfeito nem insatisfeito	Satisfeito	Muito satisfeito
1	2	3	4	5

22.Quão satisfeito você está com o apoio que você recebe de seus amigos?

Muito insatisfeito	Insatisfeito	Nem satisfeito nem insatisfeito	Satisfeito	Muito satisfeito
1	2	3	4	5

23.Quão satisfeita você está com as condições do local onde mora?

Muito insatisfeito	Insatisfeito	Nem satisfeito nem insatisfeito	Satisfeito	Muito satisfeito
1	2	3	4	5

24.Quão satisfeita você está com seu acesso aos serviços de saúde?

Muito insatisfeito	Insatisfeito	Nem satisfeito nem insatisfeito	Satisfeito	Muito satisfeito
1	2	3	4	5

25.Quão satisfeita você está com o seu meio de transporte?

Muito insatisfeito	Insatisfeito	Nem satisfeito nem insatisfeito	Satisfeito	Muito satisfeito
1	2	3	4	5

As questões seguintes referem-se a com que frequência você sentiu ou experimentou certas coisas nas últimas duas semanas.

26.Com que frequência você tem sentimentos negativos tais como mau humor, desespero, ansiedade, depressão?

Nunca	Algumas vezes	Freqüentemente	Muito freqüentemente	Sempre
1	2	3	4	5

Appendix F - Pain Catastrophizing Scale

Toda a gente passa por situações de dor em certos momentos da sua vida. Estas experiências podem incluir dores de cabeça, dores de dentes, dores articulares ou dores musculares. As pessoas estão muitas vezes expostas a situações que podem causar dor, tais como doenças, ferimentos, intervenções de dentista ou cirurgias.
Queremos conhecer os pensamentos e sentimentos que tem quando está a sentir dores. Em baixo encontra-se uma lista com treze afirmações que descrevem diferentes pensamentos e sentimentos que podem estar associados à dor. Usando a escala seguinte, por favor indique em que medida tem estes pensamentos e sentimentos quando está com dores.

0 – nunca **1** – ligeiramente **2** – moderadamente **3** – bastante **4** – sempre

Quando estou com dores …

1 ☐	Estou constantemente preocupado(a) em saber se a dor terá fim.
2 ☐	Sinto que não consigo continuar.
3 ☐	É terrível e penso que nunca mais vai melhorar.
4 ☐	É horrível e sinto que me ultrapassa completamente.
5 ☐	Sinto que já não aguento mais.
6 ☐	Fico com medo que a dor piore.
7 ☐	Estou sempre a pensar noutras situações dolorosas.
8 ☐	Quero ansiosamente que a dor desapareça.
9 ☐	Não consigo deixar de pensar nisso.
10 ☐	Estou sempre a pensar no quanto dói.
11 ☐	Estou sempre a pensar que quero muito que a dor passe.
12 ☐	Não há nada que eu possa fazer para reduzir a intensidade da dor.
13 ☐	Pergunto -me se poderá acontecer algo grave.

…Total

Appendix G - Hospital Anxiety and Depression Scale

ESCALA HOSPITLAR DE ANSIEDADE E DEPRESSÃO (HAD)	
ANSIEDADE	DEPRESSÃO
1) Eu me sinto tenso ou contraído: 3 ( ) A maior parte do tempo 2 ( ) Boa parte do tempo 1 ( ) De vez em quando 0 ( ) Nunca	2) Eu ainda sinto gosto pelas mesmas coisas de antes: 0 ( ) Sim, do mesmo jeito que antes 1 ( ) Não tanto quanto antes 2 ( ) Só um pouco 3 ( ) Já não sinto mais prazer em nada
3) Eu sinto uma espécie de medo, como se alguma coisa ruim fosse acontecer: 3 ( ) Sim, e de um jeito muito forte 2 ( ) Sim, mas não tão forte 1 ( ) Um pouco, mas isso não me preocupa 0 ( ) Não sinto nada disso	4) Dou risada e me divirto quando vejo coisas engraçadas: 0 ( ) Do mesmo jeito que antes 1 ( ) Atualmente um pouco menos 2 ( ) Atualmente bem menos 3 ( ) Não consigo mais
5) Estou com a cabeça cheia de preocupações: 3 ( ) A maior parte do tempo 2 ( ) Boa parte do tempo 1 ( ) De vez em quando 0 ( ) Raramente	6) Eu me sinto alegre: 3 ( ) Nunca 2 ( ) Poucas vezes 1 ( ) Muitas vezes 0 ( ) A maior parte do tempo
7) Consigo ficar sentado à vontade e me sentir relaxado: 0 ( ) Sim, quase sempre 1 ( ) Muitas vezes 2 ( ) Poucas vezes 3 ( ) Nunca	8) Eu estou lento para pensar e fazer as coisas: 3 ( ) Quase sempre 2 ( ) Muitas vezes 1 ( ) De vez em quando 0 ( ) Nunca
9) Eu tenho uma sensação ruim de medo, como um frio na barriga ou um aperto no estômago: 0 ( ) Nunca 1 ( ) De vez em quando 2 ( ) Muitas vezes 3 ( ) Quase sempre	10) Eu perdi o interesse em cuidar da minha aparência: 3 ( ) Completamente 2 ( ) Não estou mais me cuidando como deveria 1 ( ) Talvez não tanto quanto antes 0 ( ) Me cuido do mesmo jeito que antes
11) Eu me sinto inquieto, como se eu não pudesse ficar parado em lugar nenhum: 3 ( ) Sim, demais 2 ( ) Bastante 1 ( ) Um pouco 0 ( ) Não me sinto assim	12) Fico esperando animado as coisas boas que estão por vir: 0 ( ) Do mesmo jeito que antes 1 ( ) Um pouco menos do que antes 2 ( ) Bem menos do que antes 3 ( ) Quase nunca
13) De repente, tenho a sensação de entrar em Pânico: 3 ( ) A quase todo momento 2 ( ) Várias vezes 1 ( ) De vez em quando 0 ( ) Não sinto isso	14) Consigo sentir prazer quando assisto a um bom programa de televisão, de rádio ou quando leio alguma coisa: 0 ( ) Quase sempre 1 ( ) Várias vezes 2 ( ) Poucas vezes 3 ( ) Quase nunca
